at a wide range of impact energies covering various particle sizes and velocities. However, it can be concluded that this plot format is not well suited to accommodating high levels of uniform corrosion in the presence of low energy and low concentrations of solid impacts. The approach assumes that all mass loss (mechanical and electrochemical) is generated by the impacting particle, and hence, all the erosion-corrosion ( $T$ ) data lie well above the  $E$  power law fit (straight line on **Figure 16**). As erosion becomes more influential (i.e., higher KE or higher sand concentrations), the data begin to approach the  $E$  power law fit, that is, the data move from left to right for increasing KE and vertically down for increasing sand concentration.  $E_k$  is defined as

$$E_k = 2/3\pi r_p^3 \rho_p U_p^2 \quad [23]$$

where  $r_p$  is the particle radius,  $\rho_p$  the erodent particle density, and  $U_p$  the impact velocity. Care should be taken as experimental evidence shows that erosion rates can be dependent on  $U_p^n d^y$  where  $U_p$  is the particle velocity and  $d$  is the particle diameter, and  $n$  and  $y$  are far removed from 2 to 3 assumed in the simple energy approach seen earlier.<sup>55</sup>

The main parameters of concern for erosion relate to the solid particle–target interactions and hence the number of particles impinging, individual particle

energies, particle impingement angles, particle-to-target hardness ratios, and the shape of the particles. Near wall particle–particle interactions can also severely influence erosion rates when the volume concentration of solid particles present is high.

Finnie<sup>56</sup> developed an erosion model based on cutting wear mechanisms of the form:

$$V_u = C_1 \frac{M_p U_p^2}{4\sigma} f(\alpha) \quad [24]$$

where  $C_1$  is an arbitrary constant denoting the proportion of particles that cut the surface. Gane and Murray<sup>57</sup> found a value of  $C_1 = 0.5$  and gave reasonable predictions. Keating and Nesic,<sup>58</sup> in numerically predicting erosion-corrosion in bends and sudden expansions by two-phase flows (liquid–solid), used a modified Finnie approach based on earlier work by Bergevin.<sup>59</sup> This approach incorporated the concept of a critical velocity for plastic deformation,  $U_{cr}$ . They substituted  $(U_p \sin \alpha - U_{cr})$  for the impact velocity in eqn [24] to give

For low angles ( $\alpha \leq 18.5^\circ$ )

$$V_u = \frac{M_p (U_p \sin \alpha - U_{cr})}{2\sigma} \times \left[ U_p \cos \alpha - \frac{3}{2} (U_p \sin \alpha - U_{cr}) \right] \quad [25]$$

**Figure 16** Comparison of volume loss per impact against particle impact KE (slurry pot)<sup>54</sup> and jet impingement studies.<sup>31</sup> The  $\Delta$  indicates erosion–corrosion data, displaying the two sets of data (concentration and velocity) presented in previous plots.  $E_{pot}$  and  $E_{jet}$  are taken as mechanically nominated erosion from the slurry pot and jet impingement rigs respectively and  $T_{pot}$  is the erosion–corrosion data from the slurry pot.

For higher angles of impingement

$$V_u = \frac{M_p (U_p \sin \alpha - U_{cr})^2 \cos^2 \alpha}{12\sigma \sin^2 \alpha} \quad [26]$$

Bitter<sup>60</sup> quotes a value of  $U_{cr} = 0.668 \text{ m s}^{-1}$  for steel. Keating and Nesic used this value to successfully predict erosion rates in a sudden expansion and found the original Finnie model not to be so accurate. However, they modeled erosion-corrosion damage in a U-bend, using the original Finnie model as the modified version yielded no erosion due to the low particle velocities involved. Keating and Nesic concluded that their modeling needs more experimental validation before further refinements can be made.

Erosion models typically recognize that two erosion mechanisms act, cutting and deformation erosion, with discrete models representing each, such as the Neilson and Gilchrist erosion model used for rocket motor nozzles.<sup>61</sup> Such models have been successfully used by Forder<sup>62</sup> and Wood and Jones<sup>63–67</sup> to predict erosion of internal components within choke valves and slurry ducts. The cutting erosion model for low impact angles was first proposed by Finnie<sup>56</sup> and later modified by Hashish.<sup>55</sup> The deformation model was proposed by Bitter<sup>60</sup> and is thought to be applicable at higher impact angles ( $30^\circ$ – $90^\circ$ ). Particle shape and material properties for both particle and target have been included, which earlier simpler models have not considered. As the particle impingement angles are predicted to be below  $10^\circ$ , for critical components such as straights and bends, see Wood and Jones,<sup>63–67</sup> the contribution to the overall wear rate from deformation mechanisms can be ignored, and hence, the

volumetric erosion per impact can be given by the modified Hashish model only

$$V_u = \left\{ \frac{100}{2\sqrt{29}} r_p^3 \left( \frac{U_p}{C_k} \right)^n \sin 2\alpha \sqrt{\sin \alpha} \right\} \quad [27]$$

where  $n = 2.54$  and

$$C_k = \sqrt{\frac{3\sigma R_f^{0.6}}{\rho_p}} \quad [28]$$

Experimental studies on pipe systems show variation of the erosion mechanism and location with flow regimes. Wood and Jones<sup>63–67</sup> show erosion damage of AISI 304L stainless steel pipe components with a nominal wall thickness of 5 mm from a horizontal pipe loop tests. The pipes were of 80 mm nominal bore, although the actual mean of a series of measurements was 77.8 mm. The erosion of the bend with the greatest curvature of the whole loop ( $R_c/D = 1.2$ ) was analyzed along with its upstream straight.

Figure 17 shows the top internal surfaces (12 o'clock position) of the straight pipe after 210 h of slurry testing at  $3 \text{ m s}^{-1}$  with an asymmetric slurry flow of 10% (w/w) sand of 500–1400  $\mu\text{m}$  in size in water. Figure 18 shows the overall component details for the straight and bend investigated. The damage in Figure 17 is consistent with that of the as-manufactured (scaled) surface finish. There appears to be no significant erosion impact damage, although a few individual impact craters are seen due to impacts from the relatively few sand particles that are entrained into the energetic upper fluid flow. The lack of damage seen in Figure 17 is in contrast with the damage seen at the bottom of the straight pipe section as shown in Figure 19. This reflects

**Figure 17** SEM micrographs at (a) high and (b) low magnifications showing surface morphology of straight position (top A position) (after 210 h).

the asymmetry of sand burden in the flow with the majority of sand particles traveling in the bottom half of the pipe and only a few energetic particles saltating into the flow streams in the top half of the pipe.

In **Figure 19**, the impact features reveal that the erosion processes occurred by a simultaneous plastic deformation and microcutting of the stainless steel pipe surface, similar to type II cutting mentioned by Hutchings when the erodent rotates backwards on impact and efficiently machines the surface.<sup>8</sup>

Erosion of the bend outer wall at section two (shown in **Figure 18**) is even more intense as shown in **Figure 20**. The surface of the bend at position C (3 o'clock) has clearly been eroded with evidence of low-angle impingements with extensive plastic deformation and cutting (type II) resulting in the removal of the as-manufactured surface morphology. This level of damage is a result of impingement

by the larger and energetic sand particles with the bend wall and reflects the repositioning of the particle burden due to the bend geometry and resulting change in flow direction. Erosion-corrosion models should concentrate on such impact scars and their repassivation.

#### 2.15.2.3.2 Cavitation erosion

Cavitation bubble collapse close to a solid surface can damage the surface by two mechanisms: shock wave impingement and high-speed liquid microjet impingement. Shock waves are formed by the rapid collapse of the bubble, which generates very high internal temperatures and pressures that are relieved by shock wave propagation. The presence of the solid surface generates asymmetric bubble collapse and the formation of a microjet with a diameter of 10–50  $\mu\text{m}$  that impinges onto the surface at normal incidence

**Figure 18** Drawings of bend and straight sections which were mounted horizontally and subjected to asymmetric slurry flow for 210 h.

**Figure 19** SEM micrographs showing the surface morphology of the straight pipe at the bottom (position E) after 210 h. (b) shows individual impact scars from sand microcutting at low angle impingements with the pipe surface.

at  $\sim 250\text{--}300\text{ m s}^{-1}$ . Both of these processes produce localized temperature rise, high intensity turbulence, and transient high pressures of the order of  $\rho cV$ . These pressures are large enough to cause plastic deformation in most engineering surfaces. These pressures and temperatures enhance mass transport and electrochemical reactions and thereby also accelerate corrosion rates of metallic surfaces. The erosion produced by such near-wall bubble collapse is thought to be dominated by a fatigue process and thus cavitation erosion resistant surfaces tend to have high fatigue resistance.

The overall damage induced by cavitation and corrosion therefore involves the interaction of

hydrodynamic, mechanical, metallurgical, and chemical factors. The presence of oxygen and aggressive ions in the electrolyte is thought to be important parameters in controlling cavitation-corrosion rates. Liu *et al.*<sup>68</sup> show that cavitation-corrosion of CS in NaCl solutions is mainly controlled by the diffusion of oxygen to the surface and is sensitive to temperature and NaCl concentrations, see [Figures 21 and 22](#). The erosion process promotes anodic dissolution reactions, which are charge transfer (activation) controlled. The impingement of the microjets is also likely to contribute to surface activation by damaging the surface layer of CS corrosion products. They also

**Figure 20** Micrographs showing the surface morphology of bend erosion outer wall at section two and position C. Both images show impact craters with extensive plastic deformation and cutting damage.

**Figure 21** Effect of cathodic protection on cavitation-corrosion of CS. Total = cavitation-corrosion loss rate, CP = loss rate under cathodic protection (Cathodic overpotential of 450 mV), Corrosion = corrosion rate from *in situ* electrochemical measurements. Reworked data from Lui, J.; Lin, Y.; Yong, X.; Li, X. *Corrosion* **2005**, 61(11), 1061–1069.

show that the application of cathodic protection dramatically reduced the surface wastage rates.

Little systematic research appears to have been conducted on cavitation-corrosion. However, surfaces that combine high fracture toughness and corrosion resistance have typically been studied. A cathodic arc plasma ion plated Ni–Al film on AISI 1045 CS has been reported by Chang *et al.*<sup>69</sup> to show good cavitation erosion-corrosion resistance. Three coating compositions were studied, Ni–48Al, Ni–40Al, and Ni–30Al, and all increased the cavitation erosion resistance of the substrate 10 times and the erosion-corrosion resistance to 3.5% NaCl solutions two times and to 3.5% HCl solutions three times. The potentiodynamic polarization data of the coated specimens in these two electrolytes indicated that the coated specimens exhibited a more electropositive corrosion potential and a lower corrosion current density than did the bare substrate material. However, cavitation erosion

induced pitting corrosion of the substrate and this accelerated the mass loss rate of specimens (see **Figure 23**).

Chernega *et al.*<sup>70</sup> found that cyclic cavitation erosion-corrosion interactions increased the material loss of complex carbide coatings 1.5–2 times the continuous cavitation rates. They found that cyclic cavitation-corrosion wear processes on high velocity oxy-fuel (HVOF) carbide coatings based on Cr, Cr–Zr, Cr–Nb, Cr–Si, and Nb were enhanced by 10–20% in NaCl solutions compared with pure water. The cyclic cavitation-corrosion treatment enhanced the average corrosion processes over time by factors of between 2 and 4 compared with a continuous cavitation corrosion influence. This enhancement was related to the destruction of the protective surface oxide films, the removal of corrosion products, and the increase in microcracks in the diffusion coating as a result of microshocks produced by near-surface cavitation bubble collapse.

**Figure 22** Effect of cathodic protection on cavitation-corrosion of CS. Total = cavitation-corrosion loss rate, CP = loss rate under cathodic protection (Cathodic overpotential of 450 mV), Corrosion = corrosion rate from *in situ* electrochemical measurements. **2.15.2.3.3 Abrasion**

There are two types of abrasion: two-body or grooving abrasion as shown in **Figure 24(a)**, while three-body or rolling abrasion is illustrated in **Figure 24(b)**. There are various important parameters that control abrasion rates such as the hardness ratio between abrasant and target, the load per particle, the role of the fluid film and if it supports the contact load, particle entrainment, size and shape, and friability. Wear rates of rolling abrasion are generally lower than those generated by grooving abrasion. Industrial surveys place abrasion as the most common wear mechanism with over 50% of wear problems being associated with both types of abrasion.<sup>71</sup> In abrasive wear, material is removed or displaced from a surface by hard particles, or sometimes by hard protuberances or asperities on a counterface, forced against and sliding along the surface. The sources of the hard particles, which can be entrained into the sliding contact, include contaminants from the outside environment, wear debris, and oxidation products formed with the tribocontact or other chemical processes.

**Figure 24(c)** is a schematic of three-body rolling abrasion of a passive surface showing a wear rate that strips the passive film completely.

**2.15.2.4 Experimental Techniques**

**Table 4** lists the variety of experimental techniques used to study wear-corrosion interactions or aspects of these interactions. Most are either corrosion cells attached to wear testers or attempts to modify corrosion cells to induce some tribological contact (i.e., scratch test or adding slurry in a rotating disc/cylinder electrode). This is not ideal as experimental setups should reflect the best approach for wear and corrosion measurements and should be designed specifically and should not be just a modified existing tribotester.

**2.15.3 Tribocorrosion Mechanisms**

The interaction between tribological and electrochemical corrosive effects causes materials to corrode

**Figure 24** (a) and (b): Schematics of two-body grooving and three-body rolling abrasion, (c). Depassivation of a passive surface by three-body rolling abrasion removes the passive layer and some substrate material revealing bare metal surface.

**Table 4** Experimental techniques used to study wear-corrosion interactions or aspects of these interactions

	<i>Technique</i>	<i>Parameters evaluated</i>	<i>Comment</i>
Engineering-based rig with added electrochemical cell	Pin-on-disc, block on cylinder	Friction, linear wear, temperature, wear scar, electrochemical parameters, current/potential versus time, polarization, <i>in situ</i> AC techniques (EIS)	Can generate complex electrochemical outputs and functionality of electrochemical cells – needs careful scrutiny
	Reciprocating pin on plate		
Electrochemical rig with mechanical elements added	Abrasion and microabrasion		
	Continuous grinding		
	Instantaneous fracture <sup>72</sup>		
	Scratch tester <sup>73</sup>		
	Rapid strain <sup>74,75</sup>		
	Guillotine cutting <sup>76</sup>		
	Triboellipsometry <sup>77</sup>		
	Cavitation hydrodynamic and vibrating horn)		Vibrating horn not representative of hydrodynamic cavitation erosion
	Impinging fluid jet/slurry jet	Peak current densities (passive and nascent), surface potential, repassivation rates, wear rate, volume loss per impact, friction, surface temperature	Uniform current distribution but shear rate varies with radius
	Pipe flow		Nonuniform flow/mass transfer distribution, rough surfaces, nonuniform current distribution
	Rotating disc (laminar)		Nonuniform current distribution, shear rate varies with radius of disc
	Rotating cylinder (turbulent)		Uniform current distribution but smooth electrode surface

at a substantially higher rate than those experienced under static or quiescent conditions.

### 2.15.3.1 Mechanical–Electrochemical Interactions

This section focuses on erosion-corrosion, abrasion-corrosion, and sliding wear-corrosion interactions as there is published work in these areas. The effects of the environment on the wear-induced fatigue life are not well researched and thus are not well understood and will not be reviewed further but the readers are referred to Sethuramiah<sup>78</sup> for a review of related work.

#### 2.15.3.1.1 Erosion-corrosion

There are several possible regions of erosion-corrosion interaction between different flow regimes and corrosion. The most significant erosion-corrosion regions are where turbulent slurry flow and corrosion overlap and where cavitation interacts with corrosion, although it is possible that solids entrained into laminar flows could induce erosion-corrosion if their impact energy is sufficient to cause plastic deformation of the surface or puncture the tribofilm.

Figure 25 shows the mass loss rates for various sand concentrations for CS in 0.1 M NaOH solution for erosion rates and in 3.5% NaCl solution for erosion-corrosion rates.<sup>54</sup> These results were

obtained at  $7 \text{ m s}^{-1}$  fluid stream velocity and at  $40^\circ\text{C}$ . The erosion rates  $E$  (0.1 M NaOH solution results) show a nonlinear increase with increasing velocity. The static corrosion rate  $C$  is shown on the far left and this plus the erosion rates at the various velocities should equate to the erosion-corrosion rates  $T$  at the various velocities if no synergistic effects are present. However, as seen, the synergy terms goes negative and the interactions between  $E$  and  $C$  are, therefore, antagonistic at 0.5 w/w% sand concentration ( $T < (E+C)$ ), while a synergy is present for higher concentrations ( $T > (E+C)$ ).

**Figure 25** Experimental results for sand concentration variation at  $7 \text{ m s}^{-1}$  (294  $\mu\text{m}$  silica sand at  $40^\circ\text{C}$ ). The exposed surface area of the sample to erosion was  $3.4 \text{ cm}^2$ . Reproduced from Harvey, T. J.; Wharton, J. A.; Wood, R. J. K. *Tribology – Mater. Surf. Interfaces* **2007**, 1(1), 33–47.

**Figure 26** shows results for the same material as **Figure 25** at 0% and 1% (w/w) sand concentrations for a variety of velocities at  $40^\circ\text{C}$ .<sup>54</sup> This shows that erosion rate  $E$  is dependent on  $V^2$  but that the erosion-corrosion rate  $T$  is not linearly dependent on either  $V$  or  $V^2$ . At  $3 \text{ m s}^{-1}$  there is an antagonism, while at higher velocities a synergy is seen due to the presence of surface residual stresses and scales (layers) generated by the drawing processes used to manufacture these cylindrical samples.

When corrosion rate is partially or wholly controlled by mass transfer of reactant or product from the surface, then local conditions under erosion may well influence the mass transfer kinetics (measured by the mass transfer coefficient  $k_m$ ). Under such conditions the corrosion will be controlled by the mass transfer (typically diffusion processes) and the driving concentration gradient (relative concentrations of active species near surface compared with free stream concentrations).<sup>79</sup> Both the mass transfer and concentration gradient will be affected by solid particle impingement that influences the local fluid flow field and increases surface roughness. Erosion will also increase the surface area wetted by the corrosive electrolyte and could establish microgalvanic cells on the surface with damaged areas being anodic to the passive and (cathodic) unaffected areas.

The relationships between fluid mechanics and induced flow patterns for both open and closed fluid systems are covered elsewhere.<sup>80</sup> It is important to

**Figure 26** Experimental results for free stream velocity variation at 0% and 1% by weight sand concentration (294  $\mu\text{m}$  silica sand at  $40^\circ\text{C}$ ). Reproduced from Harvey, T. J.; Wharton, J. A.; Wood, R. J. K. *Tribology – Mater. Surf. Interfaces* **2007**, 1(1), 33–47.

understand the near-wall flow conditions if erosion-corrosion rates and locations are to be accurately quantified for engineering components. In particular, the development of eddy structures in turbulent flows through lateral momentum transfer between fluid elements, which in turn disrupt the turbulent boundary layers that are developed within near-wall flows,<sup>81–83</sup> requires particular attention as such eddies can develop localized damage patterns on solid surfaces that can lead to an accelerated loss of fluid containment and thus considerably decrease component life. An example is given in the following section, namely rippling in pipe flows

#### **Rippling of pipe surfaces by erosion-corrosion induced by near-wall turbulence**

For multiphase flows (solid–liquid), it is assumed that initially the turbulent eddy pattern in the flow is determined by the surface roughness generated by the finishing of the pipe (see **Figure 27(a)**). The ability of the sand particles to erode is largely determined by the bulk flow but will result in the modification of the surface roughness. The initial surface roughness is thus replaced by the roughness resulting from individual erosion events. In ductile materials, such as stainless steels, this roughness will be in proportion to the impact scar dimensions (**Figure 27(b)**). These in turn give rise to a new eddy pattern in the near-wall flow. During the erosion process, the sand particles have to pass through these eddies and are thereby deflected. The eddy pattern determines the angle of impact and areas of increased sand particle impact and also the corrosion rates over the surface. The concentration of damage at specific points results in the establishment of a ripple pattern, reflecting the turbulence pattern. The surface waviness increases

until a steady state is reached, at which point the surface continues to wear but the wavelength and shape remain constant (**Figure 27(c)**). The final waviness is thus a reflection of the conditions to which the material is exposed. The more severe the condition, the greater the turbulence in the boundary layer and hence the larger the wavelengths and amplitudes of surface waviness.

#### **2.15.3.1.2 Abrasion-corrosion**

The interactions between two sliding metallic surfaces that entrain abrasives between them in a corrosive environment are often complex. **Figure 28** is an attempt to schematically represent some of the possible processes involved when abrasive (body 3) enters a sliding contact between bodies 1 and 2. The abrasive can depassivate the surface by penetrating or removing the oxide layer thereby enhancing corrosion at these sites. Abrasive wear particles can be formed from either or both surfaces and can be transferred and deposited on the opposite surface (4 and 5) resulting in galvanic coupling and accelerated corrosion. The ploughing and indentation action of the abrasives on the surfaces will also induce residual stresses (tensile and compressive) and induce strains that could result in microgalvanic cells being established between affected and unaffected surface areas. Abrasion of the original oxide layer could also result in better corrosion-resistant films by producing new surfaces of different composition. For example, the good abrasive corrosion behavior of plasma-nitrided 4140 low-alloy steel reported by Lee *et al.*<sup>84</sup> was linked to the presence of the nitrided layer with a homogeneous structure of  $\epsilon$  and  $\gamma'$  phases enriched with Cr and N atoms. Under abrasion-corrosion, this layer produced a thick and dense protective layer that

**Figure 27** Ripple formation due to turbulence eddies and the influence between microroughness and eddy size: (a) initial stage with turbulence boundary layer, microroughness determined by prior machining operations; (b) intermediate stage with larger eddies due to changing surface roughness; microroughness determined by the individual erosion event; (c) final stage with steady ripple pattern, after. Reproduced from Karimi, A.; Schmid, R. K. *Wear* **1992**, 156, 33–47.

resulted in a significant decrease in corrosion current in chloride solutions.

**Figure 29** shows results from microabrasion and abrasion-corrosion tests showing a synergy for all but very low concentrations of abrasive. The lowest concentration shows a slight antagonism and under these conditions, two-body grooving abrasion dominates while at concentrations above 0.05 volume fraction the mechanism is three-body rolling abrasion. This shows that the type of abrasion can lead to different wear-corrosion interactions.

More complex and sometimes negative (antagonistic) interactions between abrasion and corrosion occur on composite surfaces.<sup>85</sup> Here, preferential corrosion at the carbide–binder interface resulted in

a 20% reduction in abrasion-corrosion wear rate compared with purely abrasive conditions. The physical mechanism of this antagonism is thought to relate to the preferential corrosion of metallic tungsten at the carbide–binder interface resulting in loose and flexible carbides and a lowering contact stresses under abrasion conditions that in turn reduces material loss, see **Figures 30 and 31**.

*In situ* electrochemical measurements made during abrasion-corrosion tests are useful as they record the kinetics of the reactions occurring and as well inform on the degree of depassivation and repassivation. **Figure 32** is a typical example of such measurements. It shows the OCP and current recorded during separate microabrasion-corrosion tests at pH 11 on a thermally

**Figure 28** Schematic illustration of the tribocorrosion contact involving two metallic samples (first body and second body) and abrasive particles (third body). Wear particles originating from the first and second bodies (4 and 5) form additional contact components. The corresponding material fluxes are also indicated.

**Figure 29** Microabrasion and abrasion-corrosion expressed as specific wear rates (SWR) of type-316 stainless steel as a function of abrasive concentration. The load was 5 N and the electrolyte was distilled water for the abrasion tests and 3.5% NaCl solution for abrasion-corrosion. The abrasive used was 4  $\mu$ m SiC.

**Figure 30** Selective corrosion of W and  $W_2C$  phases (which are formed due to decarburization of WC) around the periphery of the carbide grains in a HVOF sprayed WC-10Co-4Cr coating when exposed to an alkaline environment of pH 11 for 168 h.

**Figure 31** Schematic showing the selective corrosion of W and  $W_2C$  phases in a WC-10Co-4Cr coating.

sprayed tungsten carbide coating. The potential drops by  $\sim 60$  mV over a 250 s period once ball rotation and abrasion commences, while the current instantly increases from low freely corroding levels to  $2 \mu\text{A}$ . Both these trends show that depassivation is occurring in the wear scar area. On stopping the rotation of the ball, and thus abrasion, at 2200 s, the potential recovers in the electropositive direction and the current decreases toward the initial freely corroding levels, indicating repassivation of the wear scar.

### 2.15.3.1.3 Sliding wear-corrosion

As discussed earlier, typically passive oxide films are responsible for the corrosion resistance of metallic surfaces. However, these oxides are vulnerable when subjected to tribological contact conditions where

mechanical effects can damage or completely remove these films. This typically leads to accelerated corrosion in regions of damaged or removed oxide films.<sup>86</sup>

Ponthiaux<sup>87</sup> suggests that it is important to understand the galvanic activity resulting from worn areas surrounded by unworn areas in order to predict the performance of tribocorrosion contacts. Garcia<sup>88</sup> developed a model for the current  $I$  that flows through an electrode of area  $A$  at a given anodic potential when subjected to a reciprocating wearing contact with a frequency of  $f$  as

$$I = fA_a \int_0^{1/f} i_a(t) dt + f(A_s - A_a) \int_0^{1/f} i_p(t) dt \dots \quad [29]$$

where  $A_a$  is the worn area,  $A_s - A_a$  is the passive area,  $i_a(t)$  is the repassivation current density, and  $i_p(t)$  is the passive current density at a given anodic potential.

A model that incorporates a time constant for repassivation has been developed by Goldberg<sup>89</sup> for currents generated by scratching passive surfaces. It has the form

$$I(t) = I_{\text{peak}} \exp\left(\frac{-(t - t_0)}{\tau}\right) + I_p \dots \quad [30]$$

If Tafel behavior is applicable, then

$$I_{\text{peak}} = i_p A_r e^{[n_f/b_a]} + \frac{\delta \rho_{\text{ox}} z F A_r}{M_w \tau} \dots \quad [31]$$

where  $I_{\text{peak}}$  is the peak current ( $I_{\text{peak}} = I_{\text{max}} - I_p$ ),  $I_{\text{max}}$  is the maximum recorded current,  $\tau$  is the time constant for repassivation,  $t_0$  is the time to produce the scratch,  $I_p$  is the passive current at  $t = \infty$ ,  $i_p$  is the current density for passivation,  $A_r$  is the scratch area,  $n_f$  is the scratch overpotential,  $b_a$  is the Tafel slope,  $\delta$  is the repassivated oxide thickness,  $\rho_{\text{ox}}$  is the oxide density,  $z$  is the charge on the cation,  $F$  is Faraday's constant, and  $M_w$  is the oxide molar mass.

Mischler<sup>90</sup> developed a model for reciprocating contacts that includes the effects of load and material hardness. He modeled the anodic current  $I_{a,w}$  generated by wear induced by a hard insulating counter body.

$$I_{a,w} = K_w l f \left(\frac{W}{H}\right)^{\frac{1}{2}} \int_0^{1/f} i dt \dots \quad [32]$$

where  $K_w$  is the proportionality factor,  $l$  is the length of wear track,  $W$  is the normal load,  $H$  is the hardness of metal,  $t$  is the instant time,  $f$  is the frequency of reciprocation of contact or rotation rate if for pin-on-disc, and  $i$  is the instantaneous current density.

**Figure 32** OCP and current as a function of time during microabrasion of a 250  $\mu\text{m}$  thick D-Gun WC-10Co-4Cr coating on stainless steel 316 for a sliding distance of 90 m using 0.16 volume fraction slurry of 4.5  $\mu\text{m}$  SiC abrasives suspended in NaOH solution of pH 11. The applied load was 0.2 N and a Zirconia ball of 25.5 mm dia was rotated to give a sliding velocity of 0.05  $\text{m s}^{-1}$ . Reproduced from Wood, R. J. K. *J. Phys. D: Appl. Phys.* **2007**, 40, 5502–5521.

These three models are essentially based on the same principle but involve different contact parameters. Their validity may be limited to the specific test conditions/rig geometry used in their development. More complex models are being developed for tribocorrosion interactions in aqueous sliding contacts,<sup>91</sup> and these will be explored in the following section. However, it is extremely important to recognize the roles of reactive species in the tribological processes. Jiang and Stack<sup>92</sup> discuss the mechanisms of wear debris generation and the roles of reactive species in the generation of wear debris during sliding wear in gaseous or aqueous environments. Low cycle fatigue was taken as an important mechanism for the generation of wear debris particles during sliding wear of metals. The generation of wear debris particles was described as a process of microcrack initiation and propagation. The presence of reactive species in the environment was taken to chemically activate reaction(s) at the crack tip that weaken(s) the bonding of atoms at the tip, increasing the rate of generation of wear debris particles. The ratio between the contact frequency and the corrosion passivation rate was found to be a very important factor in determining the dominant material loss regime for a given tribosystem. At low values, wear-induced corrosion tends to be more significant in causing the overall material loss.

However, corrosion-induced wear tends to be the dominant regime for material loss at high values.

### 2.15.3.2 Wear-Corrosion Interactions

#### 2.15.3.2.1 Mechanisms of enhanced surface degradation

These interactions can be defined as follows. The total damage under wear-corrosion,  $T$ , can be represented as

$$T = E + C + S \quad [33]$$

where  $E$  is the pure wear material loss and  $C$  is the pure corrosion rate. The synergistic effect (interactive term),  $S$ , is referred to as  $\Delta E$  or  $(\Delta C + \Delta E)$  depending on the literature source, where  $\Delta E$  is the enhanced wear loss due to corrosion and  $\Delta C$  is the enhanced corrosion due to wear.

Synergy is defined as ‘the difference between wear-corrosion and the summation of its two parts’ and can be expressed by eqns [34] and [35].

$$\Delta E = T - (E + C + \Delta C) \quad [34]$$

or

$$S = \Delta E + \Delta C = T - (E + C) \quad [35]$$

where  $T$ ,  $C$ , and  $E$  are typically gravimetric terms relating to wear-corrosion, electrochemical corrosion (*in situ*), and mechanical wear mechanisms respectively.  $C$  can be taken as the corrosion current under static conditions and  $\Delta C$  measured *in situ* when wear processes are occurring. Under erosion, more confusion exists in the literature as static  $C$  or flow only corrosion rates  $C'$  are used leading to very different values of  $S$  as shown in eqns [36]–[38].

$$T = E + C + \Delta E + \Delta C \quad [36]$$

$$T = E + C' + \Delta E + \Delta C' \quad [37]$$

$$T = E + C'' + \Delta E \quad [38]$$

where  $C'$  is the solids free flow corrosion rate and  $C''$  is the corrosion rate under wear-corrosion conditions. The ASTM G 119-93 standard is a useful guide for researchers wishing to evaluate synergy.<sup>93</sup> It should be noted that researchers working in the field of tribo-corrosion are now moving away from evaluation of and using the terms synergy and antagonism in favor of quantifying the rates of electrochemical–mechanical interactions and identifying their mechanisms and physical meaning.

Wear can mechanically strip the protective corrosion film creating fresh reactive corrosion sites and produce  $\Delta C$ ,<sup>94</sup> depending on the rate of repassivation and the integrity of the film formed. Other possible wear-enhanced corrosion mechanisms include (1) local acidification at wear sites, accelerating corrosion rates, and prohibiting film formation; (2) increased mass transport by high turbulence levels; (3) lowering the fatigue strength of a metal by corrosion; (4) anodic wear scars can cathodically polarize the surrounding unworn surfaces and destabilize passive films in these regions enhancing corrosion<sup>95</sup>; and (5) surface roughening of the specimen during wear-enhanced mass transfer effects increasing the corrosion rate.<sup>95</sup> Corrosion-enhanced wear mechanisms are also possible ( $\Delta E$ ). The  $\Delta E$  wear rate could be due to (6) the removal of work-hardened surfaces by corrosion processes, which expose the underlying base metal to erosion mechanisms<sup>96</sup>; (7) preferential corrosive attack at grain boundaries resulting in grain loosening and eventual removal<sup>97</sup>; (8) the increase in the number of stress concentration defects resulting from micropitting; and (9) detachment of plastically deformed flakes on the metal surface due to stress corrosion cracking. Corrosion can increase surface roughness, which in turn can increase wear processes. This is not a synergistic interaction.

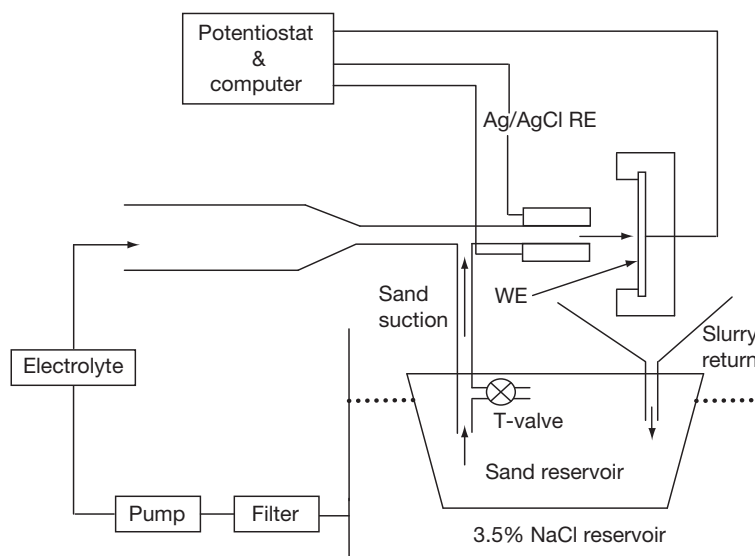

Most of these mechanisms, if dominant, would be expected to lead to positive synergy (i.e., detrimental and an acceleration of wear-corrosion). However, in some instances, an antagonism can occur. Possible mechanisms that reduce wear rates ( $-\Delta E$ ) are (10) microgalvanic (work-function difference) effect-induced inhomogeneous shot-peening<sup>98</sup> by high-velocity sand particle impacts or; (11) the presence of a soft or loosely adherent corrosion film or; (12) the blunting of the crack tips by lateral dissolution retarding the speed of crack propagation. The reduction in corrosion rates ( $-\Delta C$ ) could result from (13) a rapid corrosion film growth, scaling, or the formation of a passive film reducing corrosion rates dramatically or; (14) the generation of thermally affected film.

Malka *et al.*<sup>99</sup> give an example of where positive synergies are dominant and have looked at whether erosion enhances corrosion and/or corrosion enhances erosion in pipe loop experiments on uncoated AISI 1018 CS. The tests solutions contained 1 wt% NaCl solutions purged with CO<sub>2</sub> (partial pressure of 1.2 bar) and 2 wt% silica sand (275  $\mu\text{m}$  in size). They found that erosion enhances corrosion and corrosion enhances erosion but the dominant synergistic effect was that of corrosion on erosion, that is,  $\Delta E$ . For roughly equal corrosion ( $C'$ ) and erosion rates ( $E$ ), the total mass loss ( $T$ ) was equal to two to three times the simple summation of  $E$  and  $C'$ , ( $E+C'$ ), showing significant synergy under 2 m s<sup>-1</sup> flow velocities.

It has also been shown that for a variety of engineering materials the synergistic effects, which result in the damage due to separate corrosion and erosion processes, are normally greater than the sum of the individual damage processes and can accelerate material removal significantly 50 times in some cases (i.e.,  $T = 50 \times (C' + E)$ ), see Wood and Hutton.<sup>31</sup> Thus, the levels of  $S$  can be as high as 50 times the expected mass loss rate and would comprise most safety margins used in the design of fluid machinery and pipe systems.

An example of antagonism was seen in erosion-corrosion testing of naval grade cast nickel aluminum bronze (NAB) under jet impingement conditions with a 2.5% (w/w) sand/3.5% NaCl solution slurry. Figure 33 shows the rig used and Figure 34 shows the results from combined erosion-corrosion ( $T$ ), erosion ( $E$ ), and flow corrosion ( $C'$ ) tests for different sand particle kinetic energies generated under the conditions detailed in Table 5. As can be seen, the  $T$  values are less than  $E+C'$  values.

**Figure 33** Modified jet impingement slurry rig used for electrochemical measurement under flow corrosion and erosion-corrosion.

**Figure 34** Mass loss rates for cast nickel aluminum bronze (NAB) at different kinetic energies. Conditions: 2.5–3.0 w/w% silica sand concentration, 3.5% NaCl solution.

The reason for this antagonistic effect was determined by profiling the microhardness of uneroded and eroded areas to reveal an increase in surface hardness in eroded areas as shown in [Figure 35](#). Within the erosion scar, the hardness was doubled by hardening processes by the  $10^5$ – $10^6$  strain rates induced by the sand impacts. Transverse sections revealed a work-hardened layer some 125 nm thick, while for erosion-corrosion the layer was 250 nm thick and the erosion mechanisms were subtly different. How corrosion influences the depth of work-hardening is not clear but it is likely that work-hardening will change the surface potential and thereby will decrease the

corrosion reaction rate of the eroded surface as well as reduce erosion rates.

It is difficult to represent the interactive terms between wear and corrosion graphically to allow instant insight for designers and equipment operators. But some attempts at mapping are useful, particularly where quantitative terms are used for material loss rates. Such maps can also indicate the tribocorrosion regimes or dominant loss mechanism. This can be used to select more resistant surfaces or compositions. An example of such a plot for erosion-corrosion is given in [Figure 36](#). Here the corrosion loss rates ( $C'$ ) have been plotted against the mechanical loss rates given by  $(T - C')$ . This assumes that  $\Delta C'$  is negligible

**Table 5** Conditions used for the erosion and erosion–corrosion experiments (CP = cathodic protection)

Experiments	Jet velocity ( $\text{m s}^{-1}$ )	Sand diameter ( $\mu\text{m}$ )	Test solution	Re jet
Corrosion (C')	3.1–6	—	3.5% NaCl	
Erosion (E)	3.1–6	135 and 235 (mean diameter)	3.5% NaCl with CP	18415–29702
Erosion–corrosion (T)	3.1–6	135 and 235 (mean diameter)	3.5% NaCl	

**Figure 35** Hardness measurement for NAB on eroded and uneroded and back surface tested at  $6 \text{ m s}^{-1}$  with its 2D-profile. Positions (1) and (3) represent hardness measurements through the center of the erosion scar and far away from the scar respectively. Reproduced from Barik, R. C. Environmental factors affecting the marine corrosion performance of nickel aluminium bronze, PhD thesis, School of Engineering Sciences, University of Southampton, 2006.

and can be ignored. Results for CS, cast nickel aluminium bronze, and a sprayed nickel aluminium bronze coating are shown. The regimes are also shown defined by the ratio  $(T - C')/C'$ , where low values show electrochemical processes to be dominant, values between 0.1 and 1 are in the corrosion-erosion regime, while values between 1 and 10 are in the erosion-corrosion regime and values over 10 are in the mechanically dominated regime.

For abrasion-corrosion, a variation in synergy levels has been linked to the abrasion mechanism present in the contact. Figure 37 shows results from microabrasion-corrosion tests on types 304 and 316 stainless steel (UNS S30403 and S31603) and super duplex stainless steel (UNS 32760).<sup>100</sup> The levels of synergy are represented as a percentage calculated

by eqn [39] where  $C$  (passive corrosion rates) are assumed negligible.

$$\frac{S}{T} \times 100 = \frac{T - E}{T} \times 100 \quad [39]$$

The synergy levels ( $S/T \times 100$ ) are plotted against volume fraction of abrasive. The abrasive used was  $4.5 \mu\text{m}$  SiC particles. The abrasive mode is dependent on the abrasive concentration. For low concentrations of abrasive, a two-body grooving abrasion process dominates, while for higher concentrations three-body rolling abrasion processes dominate. It can be seen from Figure 37 that the synergy resulting from a two-body wear mode was highly variable as evidenced by the large degree of scatter. Both S31603 and S32760 stainless steels produced negative values

of  $S$  under this wear condition, while  $S$  was positive for S30403. The large antagonisms produced by the two-body wear mechanism may be a reflection of the differences in repassivation kinetics and/or composition of the passive films reducing the overall level of two-body abrasion.<sup>100</sup> However, the mixed-mode region shows a significant reduction in scatter for each stainless steel. Likewise all the three stainless steel types within the three-body region showed an improved reproducibility with increasing volume fraction of abrasive. Rabinowicz *et al.*<sup>101</sup> in their

**Figure 36** Erosion-corrosion regime map with electrochemical material loss versus mechanical material loss for erosion-corrosion of CS AISI 1020, HVOF Nickel Aluminum Bronze coating and cast Nickel Aluminum Bronze under jet impingement conditions with 2% (w/w) sand in seawater. Reproduced from Wood, R. J. K. *Erosion-Corrosion, Comprehensive Structural Integrity*; Elsevier: Oxford, UK, 2007.

study of abrasive wear under a three-body regime reported that three-body abrasion leads to more reproducible test results compared with two-body. Batchelor and Stachowiak<sup>102</sup> have also suggested that three-body abrasion is more effective in removing the corrosion products, and by implication any passive film present, during abrasion-corrosion. **Figure 37** also shows that under three-body wear,  $S$  generally converges with increasing slurry concentration to a uniform positive synergy of 18% for the three stainless steels.

### 2.15.3.2.2 Erosion-corrosion models

Ferng *et al.*<sup>103,104</sup> modeled erosion-corrosion in pipe flow by adding the erosion and corrosion contributions together. The erosion model was based on droplet impingement but used an oxide removal based on eqn [40] for predicting the mass of oxide removed,  $m$ ,

$$m = C_s N f(\alpha) \frac{\rho_f U_f^2}{H} \quad [40]$$

where  $C_s$  is a system constant,  $N$  is the frequency of impingement,  $f$  is a characteristic function,  $\alpha$  is the impact angle,  $\rho_f$  the fluid density,  $U_f$  is the normal velocity, and  $H$  is the pipe wall hardness.

The metal loss rate,  $M_R$ , in  $\text{mol cm}^{-2}\text{s}^{-1}$  model is based on a mixed control corrosion process of dissolution of magnetite and the mass transfer of ferrous ions  $\text{Fe}^{2+}$  giving

$$M_R = \frac{C_{eq} - C_{\infty}}{(1/2k_1) + (1/k_m)} \quad [41]$$

where  $k_1$  is the reaction rate constant,  $C_{eq}$  is the

**Figure 37** Synergy % ( $[S/T] \times 100$ ) versus volume fraction of the abrasives for UNS S30403, S31603 and S32760. Low volume fraction of abrasive gives two-body grooving abrasion while higher concentration generate three-body rolling abrasion. Intermediate concentrations caused a mixed two- and three-body mode (M on figure).

soluble ferrous ion concentration in equilibrium with magnetite,  $C_\infty$  is the soluble ferrous ion concentration in the bulk solution, and  $k_m$  is the mass transfer coefficient. The combination of eqns [40] and [41] with 3-D fluid modeling has been successfully used to predict erosion-corrosion rates of pipes and fittings and the location of erosion-corrosion attack.

Erosion damage by solid particle impact or cavitation bubble collapse to an oxide or passive film will reveal the underlying nascent surface inducing a higher activity (higher corrosion current), for a limited duration, than for the intact oxide surface. Bozzini *et al.*<sup>105</sup> employed a simple approximate model using a 'recovering target' concept similar to those used in Section 2.15.3.1.3 for sliding wear-corrosion. This erosion-corrosion model has the advantage that it can be applied to both passivating and actively corroding conditions. The impacting particles are modeled with rigid spheres of uniform radius  $r_p$ . Particle impact is assumed to be a Poisson process with parameter  $\lambda$  (impacts  $\text{m}^{-2} \text{s}^{-1}$ ). It is assumed that each impact gives rise to an alteration of the corrosion rate through a localized change in corrosion current density for a period of time, relating to a recovery to its initial state. The effective corrosion current density,  $i_{\text{corr}}$  ( $\text{nA cm}^{-2}$ ), at a given electrode potential (typically the corrosion potential) can be related to the mechanically influenced corrosion component of the synergistic damage through a coefficient  $f_a$ , (such that  $0 \leq f_a \leq 1$ ) expressing the fraction of the corroding surface, which is affected by the erosive action of impinging particles, by eqn [42]

$$i_{\text{corr}} = f_a i_{\text{act}} + (1 - f_a) i_u \quad [42]$$

where the subscripts 'act' and 'u' relate to 'activated' and 'unaffected' respectively. The current densities  $i_{\text{act}}$  and  $i_u$  are characteristic of the corroding material in the absence and in the presence of the erosive action and can be measured separately by means of suitable experiments. In general, the coefficient  $f_a$  can be defined in eqn [43]:

$$f_a = \left( \frac{\text{No. of impacts}}{\text{Control area}} \right) \times \left( \frac{\text{Damaged area}}{\text{Impact}} \right) \times \text{Recovery time} = \lambda A_a \tau \quad [43]$$

where  $A_a$  is the affected surface area and  $\tau$  is the passive recovery time.

Equation [42] indicates an accelerating element to corrosion caused by film damage or removal and is one element of the complex interactions between erosion and corrosion that needs to be understood. A similar approach that includes particle

impingement angle and assumes an exponential repassivation reaction has been developed by Lu.<sup>106</sup>

$$i_{\text{corr}} = i_s + i_{\text{peak}} \frac{\tau \dot{A}_e}{1 + \tau \dot{A}_e} \quad [44]$$

where  $\dot{A}_e$  is the normalized rate of active surface area generated

$$\dot{A}_e = \left( \frac{C_p U \sin \theta}{\rho_p V_p} \right) A_{\text{crater}} \quad [45]$$

where  $i_s$  is the stable passive current density,  $i_{\text{peak}}$  is the peak response in local current density due to impingement,  $\tau$  is the exponential decay constant,  $C_p$  is the mass of solids per unit volume,  $U$  is the impact velocity,  $\theta$  is the impact angle,  $\rho_p$  is the particle density,  $V_p$  is the particle volume, and  $A_{\text{crater}}$  is the crater area.

More recent erosion-corrosion models incorporate dynamic Hertzian impact area models and squeeze film effects in an attempt to evaluate more accurately actual areas of depassivation and actual particle impact velocities, Harvey.<sup>54</sup>

As mentioned earlier, the synergistic term  $S$  can be positive or negative (antagonistic). Bozzini *et al.*<sup>105</sup> showed that annealed CS had a more active corrosion potential before it was work hardened, resulting in  $i_u > i_a$  and by using eqn [42] showed a reduction (i.e., an antagonism) in overall corrosion rate with erosion present.

The Bozzoni model or ones of that type go some way to explain experimental trends. For example, Neville *et al.*<sup>107</sup> have shown that the corrosion current density increases with increasing solid loading (200, 400 and 600  $\text{mg l}^{-1}$ ) for UNS S31603 under an impinging jet of 3.5% NaCl at 17  $\text{m s}^{-1}$ . Synergistic effects have also been shown to be a function of impinging solid particle energy for various stainless steels (UNS S31603, S32100, S32250, and S32760).<sup>108</sup> Such results indicate that synergy is more pronounced at lower particle energies. For example, under an erosion energy of 0.02  $\mu\text{J}$  per impact, the volume loss under erosion-corrosion for UNS S32250 is ten times that for erosion alone. However, at higher energies,  $\sim 7.5 \mu\text{J}$ , the erosion-corrosion rate is only 1.4 times that for erosion alone. Under very low energy impacts, little differences between erosion and erosion-corrosion rates are recorded for passive steels suggesting that impact energies above a critical value maybe required to initiate depassivation.

There are data reported in the literature that certain erosion-corrosion test conditions producing an antagonism, while others produce a positive synergy. The author in Wood<sup>28</sup> reports antagonisms for a superduplex steel UNS S32750 in 3.5% NaCl solutions at  $E_k = 0.05 \mu\text{J}$  and  $90^\circ$  impingement angle. However, Neville and Hu observed a positive synergy on two superaustenitic stainless steels (UNS S31254 and S32654) and a superduplex steel UNS S32750, but these tests were conducted at a higher  $E_k$  of  $4 \mu\text{J}$ .<sup>29</sup> This suggests a complex relationship with synergy as a function of erosion conditions (energy) and repassivation tendency as this effects the crater size, crater shape, levels of strain rate, and passive film or oxide layer recovery time. Table 6 shows some typical values for  $E_k$  that may be generated in pipes, valves, pumps, and propulsors. It assumes average sand particles of  $100 \mu\text{m}$  in diameter and that these have velocities comparable to the average fluid velocities of the systems. Therefore, erosion-corrosion data are required at these energies if correct material selection is to be made.

Erosion-corrosion conditions can themselves develop local microgalvanic cells between eroded and uneroded surface areas. Such microgalvanic cells have been reported between erosion affected regions (depassivated) of a surface and noneroded regions (passive). For example, enhanced material loss rates due to such cells are reported by Hodgkiess.<sup>23</sup>

To summarize, Table 7 is an attempt to list the mechanisms that may influence the sign of the interactive terms namely the  $\Delta C$  and  $\Delta E$  components.

Another possible synergy mechanism for  $\Delta E$  has been suggested by Guo *et al.*,<sup>110</sup> who studied near-surface hardness changes induced by erosion strain hardening and corrosion softening on AISI 1045 CS and observed that the relative hardness degradation,  $\Delta H_v/H_v$ , could be correlated approximately with the anodic current density,  $i_a$ , as expressed in eqn [46]:

$$\frac{\Delta H_v}{H_v} = -B \log \left[ \frac{i_a}{i_{th}} \right] \quad [46]$$

**Table 6** Potential particle kinetic energies and flow velocities for marine components

	Marine component			
	Pipe	Valve	Pump	Propulsor
Velocity ( $\text{m s}^{-1}$ )	0–3	5	10	25
Particle diameter ( $\mu\text{m}$ )	100	100	100	100
Particle KE ( $\mu\text{J}$ )	0–0.007	0.02	0.07	0.44

where  $\Delta H_v = H_v^* - H_v$  and is the change of hardness due to anodic dissolution at the surface,  $H_v$  and  $H_v^*$  the hardness without and with anodic current present at the electrode surface respectively,  $B (>0)$  is an experimental constant, and  $i_{th}$  is the threshold anodic current density to induce the synergistic electrochemical-mechanical effect, that is, when  $i_a \leq i_{th}$ ,  $\Delta H_v = 0$ . However, relatively large anodic currents were employed to achieve relatively minor changes in hardness (typically 0.1%). This could be an artifact of the experimental equipment employed as a microhardness tested was performed. Thus, surface layer properties were affected by the substrate as more than 10% of the coating thickness was penetrated during measurement.

### Empirically based models of synergy

Wood and Hutton,<sup>31</sup> summarizing experimental data published on erosion wear over a wide range of solid particle and cavitation erosion experiments, found that the data fell within two groups: the medium- and high-synergy systems. The erosion-corrosion enhancement,  $S$ , was found to be closely linked to the pure erosion component  $E$ . Two expressions were derived by plotting  $S/C'$  against  $E/C'$  ratios to obtain the following expressions: For the medium-synergy group

$$\begin{aligned} 1 \frac{S}{C'} &= \exp \left[ 1.277 \ln \left( \frac{E}{C'} \right) - 1.9125 \right] \\ &= 0.1477 \left( \frac{E}{C'} \right)^{1.277} \end{aligned} \quad [47]$$

For the high-synergy group

$$\begin{aligned} 2 \frac{S}{C'} &= \exp \left[ 0.755 \ln \left( \frac{E}{C'} \right) + 1.222 \right] \\ &= 3.3940 \left( \frac{E}{C'} \right)^{0.755} \end{aligned} \quad [48]$$

### Sliding wear models

A sliding wear model proposed by Jiang *et al.*<sup>91</sup> defined the total wear-corrosion loss  $V_{cw}$  as

$$V_{cw} = (V_w + \Delta V_w) + (V_c + \Delta V_c) \quad [49]$$

where  $V_c$  is the pure corrosion loss,  $V_w$  is the material loss due to wear,  $\Delta V_c$  is the wear-induced corrosion, and  $\Delta V_w$  is the corrosion-induced wear.

They looked at material loss due to corrosion,  $V_c$ , during sliding in a corrosive environment and related this to the anodic corrosion current under the influence of wear by Faraday's law. For metals that can

**Table 7** 'Synergy' overview of processes that could lead to positive and negative interactive effects between mechanical and electrochemical processes present under erosion-corrosion conditions

Factor	Positive interaction	Negative interaction
Critical impact energy	Above critical impact energy to penetrate/damage passive/product film/coverage. Results in increased charge transfer at the liquid/metal interface	Below critical impact energy. Results in reduced charge transfer at the liquid/metal interface as film composition could be influenced by impact
Surface roughness, $R_a$	Roughening effects on mass transfer coefficients unknown but $k_m$ is likely to increase with increasing $R_a$ . The Silverman review <sup>109</sup> suggests that the mass-transfer dependence on Reynolds number is affected by surface roughness as $k_m \propto Re^{0.9}$ with solids eroding the surface compared to $k_m \propto Re^{0.65}$ for solids-free flows for rotating cylinder work due to roughening effects on the surface. Roughness may promote microturbulence, affecting the local double layer. Roughness could also promote local microelectrode behavior (potential field distortion) at the tips of impact craters	Roughness influences the contact mechanics of angular solid particle impingement. Increased roughness could reduce contact stresses and thereby the near and far field stress distributions
Plastic deformation/strain	Plastically deformed and stressed surfaces enhance corrosion processes. Corrosion causes premature detachment of plastically deformed or strain hardened impact crater lips	
Increased or unsteady hydrodynamics or turbulence	Unsteady hydrodynamics leads to instability of the double layers (nonsteady state) and unsteady driving concentration gradients of active species	High concentrations of solid particles could block the surface from incoming particles. Particle-particle interaction alters impact conditions
Contact temperature	Local surface (flash) temperatures could be significantly higher around and within impact craters which could accelerate corrosion rates	Local surface (flash) temperatures could influence oxide film composition and microstructure and thus could produce more erosion resistant films
Localized corrosion	Pitting and microgalvanic corrosion cells due to localized defects in the passive layers induced by erosion or exposure of inclusions or voids. Crack systems would also be vulnerable to crevice corrosion attack and accelerated crack propagation. Microgalvanic corrosion cells could be formed between erosion craters and surrounding unaffected areas	Strain-induced shift in surface potential in the electropositive direction
Multiphase surfaces	Corrosion of interface – potential to lose bond integrity between hard and binder phases, binder recession due to corrosion leaves hard phase loose to be removed by mechanical action. These interactions could also apply to splat boundaries which exist after spraying	Substrate corrosion products can eject via interconnecting pores onto the coating surface, reducing erosion rate
Passive film state	Depassivation: removal of air-borne oxides or oxide layers produced by passivation. Oxide layer could increase friction between impacting solid particle and the bulk substrate material	The overall recovery times for repassivation and adherent oxide layers formed by passivation are important relative to depassivation events. Oxide layers could also decrease the friction between impacting solid particle and the bulk substrate material. Alternatively denser oxide could be formed that reduces corrosion or erosion or both

Source: Partly taken from reviews by Wood<sup>31</sup> and Wang.<sup>30</sup>

passivate in the corrosion environment, the anodic corrosion current is composed of two components: (1) the repassivation anodic current density of  $i_a$  passing through the area,  $A_r$ , where the passive film

has been removed/damaged by the mechanical wear action; and (2) the passive current density of  $i_p$  passing through the rest of the apparent area of contact,  $A - A_r$ , where the passive film has been fully

developed.  $A$  is equal to the apparent area of contact, assuming that the area surrounding the wear track is insulated from electrochemical reactions. For nonpassive metals, the current density can be taken as  $i_p$ . It was assumed that a depassivation–repassivation event occurs in between two successive contact events during corrosion–wear sliding tests and that the removal of the passive films during sliding corrosion–wear occurs on the real area of contact,  $A_r$ , which depends on the mechanical properties of the material and the contact surface topographies. For sliding between two ductile rough bodies or a hard rough body sliding on a smooth ductile, the real contact area  $A_r$  is proportional to  $l(W/H)^{1/2}$ , where  $l$  is the width of the wear track.

Thus,

$$V_c + \Delta V_c = I_{ac} t A_{atom} / (zF\rho_t) \quad [50]$$

where

$$I_{ac} = A_r i_r + (A - A_r) i_a \quad [51]$$

Using eqn [32] due to Mischler

$$A_r i_r = I_{a,w} = K_w l f \left( \frac{W}{H} \right)^{1/2} \int_0^{1/f} i \, dt \quad [52]$$

where

$$i = (i_0 - i_a) \exp(-t/\tau_0) + i_a \quad [53]$$

The characteristic passivation time,  $\tau_0$ , reflects how easily the metal surface passivates. The lower the value of  $\tau_0$ , the more easily the metal tends to passivate. For nonpassive materials,  $i_0 = i_a$ , and the anodic dissolution current,  $i = i_a$ , is constant. This gives

$$V_c + \Delta V_c = [A_{atom} s / (zF\rho_t v_e)] \left\{ A_a i_a + K_a l (W/H)^{1/2} (i_0 - i_a) f \tau_0 [1 - \exp(-1/f\tau_0)] \right\} \quad [54]$$

where  $s$  is the total sliding distance,  $v_e$  is the sliding velocity,  $K_a$  is a proportionality constant, and  $f$  is the contact frequency between interacting surfaces.

This approach is coupled to the concept of micro-fatigue crack propagation where a critical time,  $t_c$ , is required for an existing microcrack nucleus to propagate a length,  $D_a$ , taken as the diameter of a wear debris particle and is then related to the microcrack growth rate,  $da/dn$ . There are various scenarios of how corrosion affects crack propagation. First, corrosion can increase the number of potential microcrack initiation sites,  $N_c$ . Second, reactive or corrosive species at the crack tip can promote the

propagation of the crack, increasing the generation rate of wear debris particles by reducing  $t_c$ . Third, the corrosive environment may also affect the average wear debris particle diameter,  $D_a$ , although it is difficult to predict how this factor will vary with the corrosion conditions. Finally, it is possible under certain conditions that wear is reduced as a result of crack-tip blunting or the formation of some wear-protective load-bearing areas from the corrosion products. However, Jiang *et al.*<sup>91</sup> considered the corrosion-enhanced microcrack propagation only.

The wear volume of a specimen is equal to the product of the average volume of a single particle and the total number of wear debris particles generated within a sliding time,  $t$ , which can be expressed by

$$V = \frac{\pi D_a^3}{6} k_d A_a t = \frac{\pi D_a^3 s}{6 v_e} k_d A_a \quad [55]$$

where  $k_d$  is the particle generation rate.

They assumed that during sliding wear, a microcrack is initiated on the wear surface and will propagate for a certain distance after each contact with an asperity from the counter surface. A wear debris particle is generated after a certain number of cycles of contact at the same spot with the encountering surface.

The critical time,  $t_c$ , for generating a wear debris particle with an average size,  $D_a$ , from an existing microcrack nucleus is related to the microcrack growth rate,  $da/dn$ , by

$$D_a = \int_0^{t_c} \frac{da}{d\tau} d\tau = \int_0^{t_c} \frac{da}{dn} f d\tau \quad [56]$$

If  $N_c$  active microcrack sites are present on a unit area of the wear surface that are ready to propagate, then the generation rate,  $k_d$ , of wear debris particles can be calculated by

$$k_d = N_c / t_c \quad [57]$$

Several factors are considered: the number of cracks that are above a critical size and thus propagate; the influence of stresses induced during the wear process; as well as corrosion fatigue processes. This process considers mechanical aspects in a reference environment, interactions of cyclic mechanical loading and the attack by the environment and sustained load crack growth; the following terms were developed:

$$k_d = (N_r + \Delta N_c) \{ g_r + g_{cfs} [1 - \exp(-1/f\tau_i)] + g_s \} f D_a^{-1} \quad [58]$$

where  $N_r$  is the number of critical microcracks that are ready to propagate to generate wear debris

in a reference environment,  $\Delta N_c$  is increment of the number of critical microcracks due to the presence of corrosion, and  $\tau_i$  is the characteristic reaction time for the reaction controlling a corrosion fatigue process.

Substituting this expression into eqn [57] gives the wear contribution  $V_{wc} = V_w + \Delta V_w$ :

$$V_{wc} = \frac{\pi D_a^2 A_a s}{6l} [N_r g_r + \Delta N_c g_r + (N_r + \Delta N_c) \times \{g_{cfs}[1 - \exp(-1/f\tau_i)] + g_s\}] \quad [59]$$

Thereby the total wear-corrosion loss, given by eqn [49], can be predicted by summing eqns [54] and [59].

## 2.15.4 Present and Future Applications of Tribocorrosion

Previous sections have focused on ‘heavy’ engineering applications and solution and models appropriate to these conditions. This knowledge and understanding have matured over the past 20 years or so. However, it may be the more subtle tribocorrosion problems that will drive further development and understanding. For example, corrosion–wear interactions can be used to control material loss for manufacturing of silicon wafers. This process is called chemical–mechanical planarization (CMP) and is an important process for building multilevel interconnections for electronic devices. CMP techniques have been developed for machining tungsten, aluminum, and copper. The fundamentals of these processes are not well understood

and are an active area of research at present. The supporting electrolyte used in manufacturing is acidic and oxidizing leading to material removal by a cyclic process of passivation–film abrasion followed by repassivation and then passivation–film abrasion and so on. These are similar to wear–corrosion processes discussed earlier in the chapter.

### 2.15.4.1 Chemical Mechanical Polishing (CMP)

Figure 38 illustrates the general process with the silicon wafer typically being loaded horizontally and pressed onto a rotating conditioning pad with the contact between the wafer and pad being lubricated by a slurry. The wafer holder is itself rotated as well.

The roles of mechanical abrasion and electrochemical dissolution during CMP of aluminum have been studied by Tsai and Huang.<sup>111</sup> They found, as expected, that the total metal removal rate and the electrochemical dissolution rate of aluminum in 5 vol% phosphoric acid + 0.5 M citric acid solution (pH 4) increased with increasing contact pressure and specimen rotation speed. However, the contribution of electrochemical dissolution to the total removal rate of aluminum was less than that produced by mechanical abrasion. They also detected metallic aluminum in the solution, indicating that the passive film was not the sole material removed under the chemical–mechanical abrasion condition but some wear of the parent material had occurred.

The influence of the type of conditioning pad used has been studied by Tan *et al.*<sup>112</sup> They studied three

**Figure 38** Schematic of a CMP set-up with a rotating wafer loaded against a rotating conditioner pad supported by a base plate.

types of conditioners: (1) bonded by electroplating nickel; (2) brazing Ni–Cr alloy; and (3) diamond-like carbon (DLC) film deposition on a brazed conditioner. They found that after wear-corrosion testing, the DLC film deposited on the conditioner surface of brazed Ni–Cr alloy exhibited better overall performance in terms of a higher removal rate. The pad suffered a lower wear loss and a better corrosion resistance compared with the other two conditioners.

Ziomek-Moroz *et al.*<sup>113</sup> researched into CMP of different metallic thin films, such as tungsten and copper in aqueous media. They emphasize the importance of constructing wear-corrosion maps for these complicated tribocorrosion-metallic thin film systems. The wear component followed the Preston wear equation,<sup>114</sup> namely

$$b = \int_{t_1}^{t_2} kpU dt \quad [60]$$

where  $b$  is the wear depth developed between time  $t_1$  and  $t_2$ ,  $k$  is a wear factor,  $p$  is pressure, and  $U$  is the relative velocity of the workpiece contact point with respect to the tool contact point. Equation [60] can be rearranged in terms of volume loss ( $V$ ), normal applied load ( $W$ ), and sliding distance ( $L$ ), as shown in eqn [61].

$$k = \frac{b}{\int pU dt} = \frac{b}{pL} = \frac{bA}{WL} = \frac{V}{WL} \quad [61]$$

Ziomek-Moroz *et al.* found that the synergism between corrosion and erosion during CMP of thin metallic films is a key factor in controlling the polish rate and makes this process very complex. For the CMP of tungsten and copper, the presence of a passive protective film on the metal surface plays a critical role in successful planarization. Therefore, understanding the corrosion mechanisms that control both the polish rate and the passivation behavior of the thin films are critical in controlling CMP.

The direct planarizing of tungsten by wear processes is difficult because of its high hardness. Therefore, an effective approach has been developed to facilitate planarizing of a tungsten surface by removing a continuously growing passive film on tungsten when exposed to a low-pH potassium ferricyanide slurry. Since the passive film is softer than tungsten, this chemical mechanical planarization process is effective. Akonko *et al.*<sup>115</sup> have investigated the corrosion, wear, and corrosive wear behavior of tungsten in  $K_3[Fe(CN)_6]$  slurries. The tungsten removal rate increased with increasing slurry pH and surface potential.

## 2.15.4.2 Erosion-Corrosion

In order to gain further understanding of the effects of erosion-enhanced corrosion,  $\Delta E$ , electrochemical noise techniques are being used.<sup>116</sup> These measurements allow current and/or potential perturbations about the mean corrosion current to be analyzed without grossly polarizing the surfaces. These perturbations are thought to provide valuable information on the extent of passive film rupture and repassivation during flow-enhanced corrosion and erosion-corrosion. Although individual impacts or pitting events are difficult to resolve, the result of multiple impacts or pits as over time is useful as a diagnostic tool to detect possible surface degradation mechanisms.

Figure 39 shows a corrosion flow cell designed for electrochemical noise analysis for pipe flow with no solids present in the fluid. Typically, two ‘nominally identical’ working electrodes are used and their potential noise recorded relative to a reference electrode, together with the current noise between the two working electrodes. Figure 40 shows typical potential and current responses at a pipe Reynolds number of 2000 (just around the transition from laminar to turbulent flow) on type-304 stainless steel in 3.5% NaCl solution.

Sasaki and Burstein observed current transients for single-particle impacts<sup>117</sup> on passive stainless steels, illustrating that monitoring such transients can provide direct information on the erosion-corrosion processes. A simple way to analyze such data is to take the standard deviation of the current traces under flow corrosion,  $\sigma_c$ , and under erosion-corrosion,

**Figure 39** Schematic of electrochemical flow cell and measurement set-up.

$\sigma_T$ . Attempts are currently being made to link the standard deviation ratio  $\sigma_c/\sigma_T$  to synergy, see [Figure 41](#).

Caution should be applied to any electrochemical measurement under erosion-corrosion conditions. Other issues make electrochemical analysis and its comparison to synergy difficult. These include the possibility of local film currents between anodes/cathodes,<sup>118</sup> which will not be seen by ECN measurements or by potentiostats and the effects of charging/recharging double-layer currents due to fluctuating local events.

### 2.15.4.3 Biotribocorrosion

#### 2.15.4.3.1 Dentistry

The use of artificial materials to replace natural dental tissue is common in dentistry. Due to health

aspects, there is concern about the risks that the corrosion and wear of these materials may induce. Linear wear and the release of wear particles are especially of interest. The insight into wear-corrosion processes in dentistry is, however, still in its infancy. Lambrechts *et al.*<sup>119</sup> give an overview of the degradation processes that occur on artificial materials used in dentistry, especially in restorative dentistry. Light-cured composite resins of inorganic silica fillers in organic (polymer) resins are currently seen as viable alternatives to amalgam. Wear of dental composite resins involves adhesion, abrasion, attrition, chemical degradation, and fatigue, see [Table 8](#). These mechanisms often act simultaneously and/or sequentially and interact with each other in a complex form, making the prediction of loss rates difficult.

Wear in the filled composites occurs by a complex set of processes involving tribochemical reactions between the filler particles and water, formation of surface films containing a mixture of filler fragments and reaction products, and film delamination, as well as dissolution of the reaction products.<sup>120</sup>

The wear behavior of a dental ceramic composite containing 92 wt% silica glass and alumina filler particles in a polymeric resin matrix has been examined by Nagarajan *et al.*<sup>121</sup> Wear tests confirmed the presence of Al and other elemental constituents of the filler particles. It is proposed that three simultaneous processes occur at the sliding contact: tribochemical reactions and film formation, dissolution of the reacted products, and mechanical removal of the film by microfracture. At low loads, wear occurs primarily by a tribochemical mechanism, that is, formation and dissolution of the reaction products.

Lewis and Dwyer-Joyce<sup>122</sup> have reviewed the current understanding of wear of enamel and dentine in teeth and highlight the major influencing factors. They looked at various tribological conditions to which teeth are exposed. These include noncontact between opposing teeth, contact but no sliding, and contact with sliding between opposing teeth. They emphasize that the largest single influencing factor is that of the chemical environment and this interacts with a synergistic effect with all wear mechanisms to enhance material loss rates. Research has shown that increasing acidity reduces both hardness and elastic modulus of enamel in an appropriate linear relationship without load or sliding between teeth. Material loss for both enamel and dentine increases with decreasing pH generated by acids found in soft drinks. Citric acid adjusted by NaOH (to the required pH range between 2 and 6.5) and citric acid with titratable

**Figure 40** Electrochemical current and potential noise for AISI 304L in 3.5 wt.% NaCl solution.

**Figure 41** Standard deviation of erosion-corrosion current noise divided by the standard deviation of corrosion current noise as a function of the synergy as presented by gravimetric S/T%. Data from erosion-corrosion jet impingement tests on HVOF nickel aluminum bronze and aluminum alloy coatings in sand/3.5% NaCl slurries.

**Table 8** Dental wear and wear-corrosion processes

<i>Wear mechanism</i>	<i>Effect</i>	<i>Driving mechanism</i>	<i>Cause</i>
Abrasion	Occlusal material wear	Frictional surface interactions three-body abrasion	Toothbrush/paste food bolus
Attrition	Changes surface texture	Sharp asperities two-body abrasion	Antagonistic surface 50% harder than the wearing surface
Chemical wear	Degrades silane couplings in composites	Wetting	Food or saliva
Surface fatigue	Surface layer delamination and severe roughening	Rolling contacts and cyclic loads	Subsurface stress concentrations
Adhesive	Platelet-shaped wear transferred to antagonistic surface which can either reduce or enhance wear rates	Asperity–asperity interaction	Shear stresses

acidity give the highest loss rates. In the contact without sliding between teeth, the enamel loss increases with increasing load or cyclic load. For contacts with sliding, a nonlinear relationship is seen, with wear rates decreasing as the pH drops from 7 to 3 but increasing when the pH is further decreased to 1. Until now, these synergistic and antagonistic effects between the chemical and mechanical tooth wear have not been properly investigated.

Dental implants, on the other hand, are used to replace teeth lost due to decay, trauma, or periodontal diseases. These implants are subject to micromovements at the implant–bone interface or implant–porcelain interface due to the transmitted mastication loads and also subject to the aggressive oral environment. Such implants are thereby subject to tribocorrosion that can lead to implant failure. Vieira *et al.*<sup>123</sup> studied titanium grade 2 in contact with low-pH artificial saliva under fretting conditions and with different inhibitors. They found that the addition of citric acid or anodic inhibitor to artificial saliva resulted in a slight improvement in the tribocorrosion behavior of Ti. No significant differences were observed in the wear rate per dissipated energy, but a lower wear volume loss was obtained that can be attributed to the slightly lower corrosion rate observed in these solutions during the fretting tests. This increased protection was attributed to the oxidation and reduction reactions occurring in the contact area during fretting. They noted that the tribolayers formed in the contact became more stable after ~7000 cycles in solutions containing citric acid or anodic inhibitor, and resulted in lower coefficient of friction and a lower corrosion current. The addition of a cathodic or an organic inhibitor to the artificial saliva resulted in a

**Figure 42** Total hip replacement joint in CoCrMo.

deteriorating performance of the titanium. Both an increase in the wear volume loss per unit-dissipated energy and a significantly higher corrosion rate during fretting tests were observed in these solutions.

The tribocorrosion of orthodontic archwires is also a growing research area and various stainless steel archwires have been investigated by Berradja.<sup>124</sup> They found the fluctuations in potential and current during fretting–corrosion are more pronounced at increased sliding frequency than at increased applied normal loads.

#### 2.15.4.3.2 Replacement joints

Researchers are becoming increasingly interested in metal-on-metal (MoM) joint implants, see [Figure 42](#), with studies being focused on their wear and corrosion (ion release) behavior. The corrosion, wear, and wear-corrosion behavior for three materials (high-carbon CoCrMo, low-carbon CoCrMo, and UNS S31603) have been discussed by Yan *et al.*<sup>125</sup> In the steady state regime, 20–30% of the material

**Figure 43** Electrochemical current noise obtained in microabrasion-corrosion test on as-cast CoCrCo ( $1.0 \text{ g cm}^{-3}$  SiC) in 0.9% NaCl, phosphate buffered saline (PBS) solutions, 25% and 50% bovine serum (BS) at  $37^\circ\text{C}$ . Reproduced from Sun, D. Wharton, J. A.; Wood, R. J. K.; Ma, L.; Raithforth, W. M. Microabrasion-corrosion of cast CoCrMo alloy in simulated body fluids, presented Leeds-Lyon 2007, Tribol. Int. submitted for publication.

degradation was attributed to corrosion-related damage. High-carbon CoCrMo showed excellent corrosion, wear, and corrosion-wear resistance and therefore delivered the best overall performance in terms of a lower wear rate, a lower friction coefficient, and a higher resistance to corrosion. Proteins in the joint fluids are thought to play a key role but this mechanism is not well understood.

Sinnett-Jones *et al.*<sup>126</sup> investigated the synergistic effects of corrosion and wear of surgical grade cast F-75 cobalt–chromium–molybdenum (CoCrMo) alloy. Microabrasion-corrosion identified depassivation and repassivation processes and showed strong synergistic effects ranging from negative to positive. The synergistic levels appear to be dependent on the integrity of the passive films and the repassivation kinetics.

The role of protein in the tribocorrosion of metal implants is not well understood but initial studies

**Figure 44** SEM micrographs of wear scars on as-cast CoCrMo under pure sliding conditions in (a) 0.9% NaCl, (b) PBS, (c) 25% BS, (d) 50% BS at  $37^\circ\text{C}$ . Black arrows show a carbide standing proud of the surface. The white arrows show possible protein and wear debris on the worn surfaces. Polished wear scars, as opposed to two-body abrasion seen in (a) and (b), were produced in proteinaceous solutions indicating proteins form a lubrication film which protect the surface. Reproduced from Sun, D. Wharton, J. A.; Wood, R. J. K.; Ma, L.; Raithforth, W. M. Microabrasion-corrosion of cast CoCrMo alloy in simulated body fluids, presented Leeds-Lyon 2007, Tribol. Int. submitted for publication.

show conflicting trends with corrosion being either enhanced or reduced when protein is present and adsorbed onto the articulating surfaces. Sun<sup>127</sup> has studied abrasion-corrosion of cast CoCrMo in saline (0.9% NaCl and phosphate buffer solution (PBS)) and protein containing solutions of BS. *In situ* current noise results, see **Figure 43**, show reduced current levels when proteins are present.

Using the same test geometry, but removing the abrasives, so that the alumina ball abrades the CoCrMo surface under sliding wear mode, again shows that the presence of protein alters and reduces the wear mechanism and rate as seen in **Figure 44**.

### 2.15.5 Conclusions

Tribocorrosion has only recently been recognized as an important underpinning area of corrosion and therefore is in its infancy. This chapter has defined tribocorrosion and presented the fundamental principles behind wear, flow corrosion, erosion-corrosion, cavitation erosion-corrosion, sliding wear-corrosion, and abrasion-corrosion interactions. It has shown the key material and environmental parameters that influence tribocorrosion and used examples to illustrate the performance of materials under a variety of tribocorrosion conditions. It has outlined the conditions under which tribocorrosion occurs in aqueous solutions and shown that the depassivation and repassivation kinetics within tribocorrosion conditions need to be understood or controlled if accelerated damage is to be avoided. It has discussed the motivation behind current research and presented some examples of where tribocorrosion research will play a major role in the future, such as in biotribocorrosion, manufacturing, and erosion-corrosion detection to aid condition monitoring of fluid machinery and chemical processes.

The influence of the corrosive environment is shown to be important in controlling wear and friction and the evolution of near-surface triboinduced layers, which are critical in both erosion-corrosion and wear-corrosion situations. The chapter has identified the key interactions between wear and corrosion mechanisms that occur along with some models and mapping techniques that aim at informing material selection and predict performance. However, these need major development before robust predictions can be made as our understanding of the mechano-electrochemical interactions in tribocorrosion are incomplete.

### Acknowledgments

I thank all those in my research group who helped with this chapter and particularly Dr Julian Wharton for various figures and material and his constant encouragement. I also thank Drs Terry Harvey and Mandar Thakare as well as Dan Sun (PhD student) for their help with figures.

### Glossary

**Calcite** Calcium carbonate.

**Gypsum** Calcium sulfate.

**Permanent hardness** Water hardness that cannot be removed by boiling; for example, the precipitation of calcium sulfate.

**ppm** Strictly parts per million by mass; equivalent to 1 mg of solute per kg of solvent. In dilute solutions and for practical usage, it is equivalent to 1 mg of solute per litre ( $\text{dm}^3$ ) of solvent.

**Temporary hardness** Water hardness that can be removed by boiling causing the loss of dissolved  $\text{CO}_2$ ; for example, the precipitation of calcium carbonate.

**Water hardness** A measure of the tendency of water to precipitate a solid scale; generally related to the concentration of dissolved cations (in particular calcium and magnesium) with respect to dissolved anions (in particular bicarbonate and sulfate).

## Abbreviations

**HVAC** Heating, ventilation and air conditioning

**LSI** Langelier saturation index

**PSI** Puckorius scaling index

**RSI** Ryznar stability index

**TDS** Total dissolved solids

## Symbols

**$K_{sp}$**  Solubility product

**$\Delta G$**  Free energy change

**[x]** The concentration of species 'x' is conventionally denoted by placing it in square brackets

### 2.17.1 Introduction

Metals immersed or partly immersed in water tend to corrode because of their thermodynamic instability. Natural waters may contain some or all impurities such as dissolved solids and gases, colloidal or suspended matter, and biological materials (microbes, algae). All these may affect the corrosive properties of the water in relation to the metals with which it is in contact. The effect may be either of stimulation or of suppression of either the cathodic or the anodic reaction. Thus, some metals may form a natural protective film in a specific water composition and the corrosiveness of the water to these metals depends on whether or not the dissolved species that it contains assist in the maintenance of a self-healing film (i.e., whether they are inhibiting or not).

The metals most commonly used for water systems are iron and steel. These metals often have some sort of applied protective coating; galvanized steel, for example, relies on a thin layer of zinc, which is anodic to the steel except at high temperatures. Many systems, however, contain a wide variety of other materials and the effect of various water constituents on these must be considered. Although there is increasing use of polymeric materials in water systems, metallic components are still very common and include copper, brasses, bronzes, lead, aluminum, stainless steel, and solder.

The passage of natural water through a pipe may modify the composition of the water and hence its corrosive properties. For example, dissolved oxygen or carbon dioxide may be removed partially or wholly by reaction with metals or organisms. Dissolution of a metal into water may, on the other hand, make it more

corrosive. An example of this is the attack of some waters on copper and the subsequent increased pitting corrosion of less noble metals such as iron, galvanized steel, and aluminum. This enhanced pitting is caused by the deposition of minute quantities of copper on the less noble metal, thereby setting up numerous local bimetallic corrosion cells.

Failure of the metal can be the most important effect of corrosive water, but other effects may arise from low concentrations of metallic ions produced by corrosion. Water passed through a lead pipe may contain a toxic concentration of that metal; with copper there is a greater tolerance from the toxicity point of view but staining of fabrics and sanitary fittings may be objectionable. With iron, similarly, discoloration of the water may be unpleasant and may cause damage to materials being processed. The effects of dissolved zinc in the environment have also recently become a concern.

The concentrations of various substances in drinking water or in industrial process waters in the dissolved, colloidal, or suspended form are relatively low but vary considerably. For example, a hardness of 300–400 ppm (as  $\text{CaCO}_3$ ) is sometimes tolerated in potable (drinking) public water supplies, whereas dissolved iron to the extent of  $1 \text{ mg dm}^{-3}$  would be unacceptable. On the other hand, saline waters, including seawater, estuarine water, and brines from boreholes can contain very large quantities of dissolved species; however, these last mentioned types of water are not considered in this section.

### 2.17.2 Constituents or Impurities in Water

The important constituents in natural water can be classified as follows:

1. dissolved gases (e.g., oxygen, nitrogen, carbon dioxide, ammonia, sulfurous gases);
2. mineral constituents, including hardness salts (e.g., calcium, magnesium, carbonate/bicarbonate, etc), sodium salts (e.g., chloride, sulfate, nitrate, etc.), other salts, and dissolved silica;
3. organic matter, including that of both animal and vegetable origin, oil, trade waste (including agricultural) constituents and synthetic detergents;
4. microbiological forms, including various types of algae and slime-forming bacteria.

In water analysis, determinations (except occasionally for dissolved gases) are made on the basis of mass

**Table 1** Typical water analyses (values in  $\text{mg dm}^{-3}$ )

	<i>Very soft water</i>	<i>Moderately soft water</i>	<i>Slightly hard water</i>	<i>Moderately hard water</i>	<i>Hard borehole water</i>	<i>Very hard borehole water</i>
pH	6.3	6.8	7.4	7.5	7.1	7.1
Alkalinity due to	2	38	90	180	250	470
Calcium	10	53	120	230	340	559
Total hardness	5	36	85	210	298	451
Calcium hardness	6	20	39	50	17	463
Sulfate	5	11	24	21	4	149
Chloride	Trace	0.3	3	4	7	6
Silica	33	88	185	332	400	1670
Total dissolved solids						

Source: Drane, C. W.; Oliphant, R. J. *Natural Waters*. In Corrosion, 3rd ed.; Shreir, L. L., Jarman, R. A., Burstein, G. T., Eds., 1994; chapter 2.3.

of solute to volume of solvent ( $\text{mg dm}^{-3}$ ). More strictly, parts per million (ppm) refers to mass of solute to mass of solvent but in dilute solutions, and to all practical purposes, the two units are interchangeable. In treated water for high-pressure boilers, impurities are in much lower concentrations and are measured in parts per billion (ppb, equivalent to  $1 \mu\text{g dm}^{-3}$ ).

Water analysis for drinking-water supplies is concerned mainly with pollution and bacteriological tests. For industrial supplies, a mineral analysis is of more interest. **Table 1** includes a typical selection and gives some indication of the wide range of impurities that can be found.

### 2.17.2.1 Dissolved Gases

Of the dissolved gases occurring in water, oxygen occupies a special position as it is the main cathodic reactant and can control the corrosion reaction rate if mass transport limits the arrival of oxygen to the cathode. Carbon dioxide is scarcely less important as it dissolves in water to giving rise to equilibria with carbonic acid, bicarbonate and carbonate in solution, which are important in the control of solution pH and the solubility of calcium carbonate and, hence, the calcium hardness of the water. Therefore, the quantity of dissolved carbon dioxide in solution controls the solubility of the carbonate rocks that frequently comprise the geology close to boreholes.

Nitrogen is also generally present with oxygen although, as it is significantly less soluble, the mass ratio of dissolved nitrogen to oxygen in water is not the same as in air (it is about 4:3). It has little importance in connection with corrosion, but can be a nuisance if changes in physical conditions (e.g., reduction in local pressure) bring about its release from solution.

Other gases which are occasionally present in natural water usually arise from pollution. Ammonia,

which in various forms may be present in waste waters, attacks copper and copper alloys; its presence in estuarine waters is one of the causes of corrosion of copper-based steam condenser tubes. Hydrogen sulfide may also be the result of pollution but often bacterial action (e.g., by sulfate reducing bacteria) is the main contributor. Both gases initiate and/or accelerate the corrosion of most metals.

### 2.17.2.2 Oxygen

Although other oxidants can occur in natural waters (in particular sulfur species) dissolved oxygen is probably the most significant constituent affecting corrosion; its importance lies in the fact that it is the most important cathodic reactant in neutral solutions. In surface waters, the oxygen concentration is in equilibrium with the atmosphere and, hence, approximates to saturation. Underground waters are more variable in oxygen content and some waters may be effectively oxygen-free. Contact with air, however, usually gives rise to an oxygen concentration similar to the figures in **Table 2**. The solubility is slightly less in the presence of solutes, but this effect is not very significant in natural waters containing less than 1000 ppm dissolved solids.

For many applications, notably feed-water for boilers, removal of oxygen is essential and is accomplished by physical or chemical de-aeration. For many other purposes (e.g., once-through systems, heating, cooling and ventilation, i.e., HVAC systems), however, full de-aeration is not applicable, as the water used is in continuous contact with air, from which it would rapidly take up more oxygen. In these circumstances, chemical treatment, with corrosion inhibitors for example, is necessary to restrict corrosion.

A major difficulty in chemical water treatment is that the oxygen content of the water may not be the same at all points. For example, in a thin layer of water,

between a deposit, crevice or other surface occlusion and the metal on which it is present, the oxygen can be depleted; the difference in oxygen content between the body of water and the stagnant water will then set up a corrosion current which is difficult to suppress.<sup>1,2</sup> Rather, similar conditions occur at the water line of a vessel containing water with air above it. Even if the water is conditioned to inhibit corrosion under submerged conditions, it is difficult to extend the protection to above the water line. Fluctuation in water level extends the area of localized attack.

### 2.17.2.3 Carbon Dioxide

The effect of dissolved carbon dioxide on corrosion is closely linked with the bicarbonate content of the water. In many waters divalent cations (such as calcium and magnesium) are present at significant concentration and, depending on the water chemistry and temperature may precipitate a scale onto surfaces (i.e., hard waters). The stability, or otherwise, of calcium and magnesium in solution depends on a number of factors, the most important of which are pH, dissolved total carbonate concentration (and its speciation as dissolved CO<sub>2</sub>, carbonic acid and bicarbonate) and the concentration of Ca<sup>2+</sup> and Mg<sup>2+</sup>. Any external phenomenon that reduces the solubility of the divalent cations will result in their precipitation, typically as a scale containing either calcium carbonate or magnesium hydroxide (or both).

Calcium bicarbonate requires excess carbon dioxide in solution to stabilize it; the necessary concentration depends on the other constituents of the water and the temperature. Carbon dioxide dissolves in water to give carbonic acid in the following equilibria, with the equilibrium constants ( $K_x$ ) indicated<sup>3</sup>:

However, although carbonic acid is a stronger acid than acetic acid, its concentration in solution in equilibrium with atmospheric carbon dioxide ( $\approx 385$  ppm) is relatively low and, therefore, its effect is considerably less. In the absence of dissolved carbonate species from other sources, the solution pH is therefore determined by the partial pressure of CO<sub>2</sub>:

The speciation among carbonic acid, bicarbonate ion and carbonate ion depends on the above equilibria and, hence, the pH. **Figure 1** shows calculated mole fractions of carbonic acid, bicarbonate ion, and carbonate ion as a function of pH for a fixed total carbonate concentration.

### 2.17.2.4 Water Hardness (Carbonate Species)

The usual classification of water by hardness (**Table 3**) is as follows.

The hardness figures for natural water are very varied but most natural drinking water supplies fall into two well-defined groups:

1. Upland waters of low hardness commonly retained in storage reservoirs. In the United Kingdom, these are supplied to most localities in Scotland, Wales, and the North of England.

**Table 2** Solubility of oxygen in distilled water

Temperature (°C)	Oxygen content of saturated, distilled water	
	mg dm <sup>-3</sup>	ml dm <sup>-3</sup>
0	14.16	9.90
5	12.37	8.65
10	10.92	7.64
15	9.76	6.83
20	8.84	6.18
25	8.11	5.67

**Figure 1** Calculated mole fractions of carbonic acid, bicarbonate ion, and carbonate ion as a function of pH at a total carbonate species concentration of 1 mM. Calculated with Puigdomenach, I.; *Hydrochemical Equilibrium Constant Database (HYDRA/MEDUSA)*; Royal Institute of Technology: Stockholm. Available at [www.kemi.kth.se/medusa](http://www.kemi.kth.se/medusa).

2. Underground waters of high hardness, usually derived from aquifers in chalk, sandstone or limestone strata. In the United Kingdom, these are found mainly in the East and South of England.

A few sources, most of which are derived from rivers and vary according to season, are intermediate in composition between these.

The corrosive properties of natural waters are governed by many factors and cannot be related to hardness alone, but the following trends are apparent:

1. Soft upland waters are commonly corrosive to most metals, their behavior depending to some extent on pH. They are inevitably unsaturated with respect to calcium carbonate and it is not usually practicable to modify the carbonate equilibrium to make them nonaggressive.
2. Very hard waters are usually not very aggressive provided that they are supersaturated in calcium carbonate. Underground waters with a low pH

**Table 3** Range of calcium hardness for various natural waters

<i>Calcium concentration</i>	<i>Hardness classification</i>
<50 ppm CaCO <sub>3</sub>	Soft
50–100 ppm CaCO <sub>3</sub>	Moderately soft
100–150 ppm CaCO <sub>3</sub>	Slightly hard
150–250 ppm CaCO <sub>3</sub>	Moderately hard
250–350 ppm CaCO <sub>3</sub>	Hard
>350 ppm CaCO <sub>3</sub>	Very hard

value caused by excess carbon dioxide content are, however, aggressive unless corrective treatment is applied.

3. Waters of intermediate hardness frequently contain significant amounts of other constituents and there is often a tendency for the scale formed to be loosely attached to the metal surface, permitting corrosion to occur irregularly underneath. In most waters the bicarbonate content is less than the hardness, but a few natural waters are known where the reverse is the case.

### 2.17.2.5 Other Inorganic Species

The principal ions found in natural water supplies include calcium, magnesium, sodium, bicarbonate, sulfate, chloride, and nitrate; also a few parts per million of iron or manganese may sometimes be present. From the corrosion point of view the small quantities of other anions present, for example, nitrite, phosphate, iodide, bromide and fluoride, have little significance. Although larger concentrations of some of these ions, notably nitrite and phosphate, may act as corrosion inhibitors, the small quantities present in natural waters will have little effect. Some of the minor constituents have other beneficial or harmful effects, for example, there is an optimum concentration of fluoride for control of dental caries and very low iodide or high nitrate/nitrite concentrations are objectionable on medical grounds (**Table 4**).

Dissolved ionic species will increase the ionic conductivity of water and, hence, tend to increase metallic corrosion by reducing the ohmic voltage loss between local anodes and cathodes. At low

concentration the effect on ionic conductivity dominates, although chloride will always tend to promote pitting corrosion on passive materials (e.g., stainless steel) that are protected by a thin protective scale. In the latter case, the ratio of chloride to hydroxide (or bicarbonate) can be important.<sup>4</sup> Sulfate in general appears to behave very similarly; Hatch and Rice have shown that small concentrations in distilled water increase corrosion more than similar concentrations of chloride.<sup>5</sup> In practice, high-sulfate waters may attack concrete and the performance of some inhibitors appears to be adversely affected by the presence of sulfate. Sulfates have also a special role in bacterial corrosion under anaerobic conditions.

Regarding iron- and manganese-bearing waters, the small amount of deposit formed is not likely to have much effect on corrosion. However, most iron-bearing waters contain substantial amounts of carbon dioxide which may be troublesome. Manganese-bearing waters may be of a similar type but they sometimes contain complex organic compounds of manganese for which special treatment may be needed. Substantial iron and manganese content in water will tend to promote pitting corrosion of materials such as aluminum, stainless steel and copper. Another mineral constituent of water is silica, present both as a colloidal suspension and as a dissolved species.

### 2.17.2.6 Organic Species

The types of organic matter in water supplies are very diverse; they may be present in suspension, or in colloidal or true solution and may include micro-organisms. The materials are largely derived from decaying vegetable matter but there are many other possible sources including run-off from fields and domestic and industrial wastes. Some of the worst corrosive effects ascribed to natural soft waters are attributed to a rather wide group of organic acids abstracted from peat and mosses, sometimes called humic acids.<sup>6</sup> Such waters have low pH values and are often discolored. They affect ferrous metals appreciably and also attack lead and copper. Corrosion control, either of steel or of copper, is rarely achieved solely by pH correction of such waters.

## 2.17.3 Scaling in Natural Waters

### 2.17.3.1 Controlling Factors in Scale Formation

The deposition of a scale from solution involves the nucleation, crystallization and growth of a new solid

phase. Nucleation of deposits may take place either in solution (homogeneous nucleation) or on a suitable substrate where the *local* (i.e., adjacent to the substrate) chemistry may be particularly conducive to scaling (heterogeneous nucleation). Nucleation is a thermodynamically driven process and the elementary theory predicts that nucleation requires a driving force to overcome the new phase boundary (i.e., surface) created. Thus, the formation of a new phase in a solution *reduces* the overall free energy of the system by precipitating out a supersaturated species; however, it *increases* the local free energy by formation of a new surface. Both of these processes can be modeled (for homogeneous nucleation in solution) as follows<sup>7</sup>:

$$\Delta G_{\text{tot}} = 4/3\pi r^3 \Delta G_{\text{volume}} + 4\pi r^2 \Delta G_{\text{surface}} \quad [4]$$

where  $\Delta G_{\text{tot}}$  is the overall Gibbs free energy change during nucleation;  $\Delta G_{\text{volume}}$  is the free energy change per unit volume of new species formed (which will be negative and favorable);  $\Delta G_{\text{surface}}$  is the free energy per unit surface area of the nucleus (which will be positive and unfavorable). The above equation is easily altered for heterogeneous nucleation (i.e., on a surface). Nucleation theory predicts that nuclei do not grow below a specific, critical dimension, which can be seen clearly in Figure 2.

The above thermodynamic treatment can say nothing about the kinetics of the nucleation process except that at higher supersaturation, the driving force for nucleation is greater. Once nuclei have formed, their subsequent growth is determined by a number of interacting processes, particularly the diffusion of species in solution.

**Figure 2** Variation of surface and volume free energy with nucleus size showing that a critical size is required before stable nucleation is possible.

The solubility of most scale-forming minerals decreases as the temperature increases. Therefore, such solutions will precipitate a scale directly on the heat-transfer surface because of their lower equilibrium solubility at these locations (carbonate scales that form from hard water in domestic kettles being the obvious example). Other soluble species may be scale-forming as a result of changes in pH, pressure, flow, etc. Generally, the crystallization of a scale-forming material from solution is influenced by several factors including the following<sup>8</sup>:

- Local and general supersaturation of the soluble species in solution.
- Solution temperature and particularly temperature differentials especially at surfaces where heat transfer is occurring.
- Solution pH and particularly local changes in pH at cathodic surfaces.
- Pressure, especially where the speciation is controlled by a soluble gas such as CO<sub>2</sub>.
- Flow rate, as this influences local solution temperatures and concentrations, as well as transport of reacting species to the scaling surface.
- Scale nucleation and particularly scale growth are time-dependent processes.
- Surface condition: in particular particles of dirt and rough surfaces will encourage scale nucleation and adherence.

### 2.17.3.2 Calcium Carbonate Scales

The mathematical relationship between carbon dioxide, calcium bicarbonate and calcium carbonate was historically studied by several workers, including Langelier.<sup>9,10</sup> The simpler form of his original equation is (at constant temperature)

$$pH_s = pCa + pAlk + (pK_2 - pK_s) \quad [5]$$

where  $pH_s$  is the pH at which calcium carbonate precipitates,  $pCa$  is the negative logarithm of the calcium concentration expressed as parts per million of CaCO<sub>3</sub>,  $pAlk$  is the negative logarithm of the alkalinity to methyl orange expressed in parts per million of equivalent CaCO<sub>3</sub>,  $pK_2$  is the ionization constant of HCO<sub>3</sub><sup>-</sup>, and  $pK_s$  is the solubility product of CaCO<sub>3</sub>.

This formula does not apply to pH values over 9. Also, as the term  $(pK_2 - pK_s)$  is a function of temperature and ionic strength (dissolved solids), high salinities will affect its accuracy. However, for the analysis of water at constant temperature much useful

information can be obtained from the basic thermodynamic treatment of Langelier. In order to determine whether water is supersaturated with respect to calcium ions, the Langelier saturation index of water (LSI) is defined as

$$LSI = pH - pH_s \quad [6]$$

where pH is the actual pH of the water and  $pH_s$  is the pH of saturation of calcium carbonate. If the LSI is positive the water will be supersaturated with calcium carbonate, which will, therefore, tend to precipitate as a scale. Conversely if the LSI is negative the water tends to dissolve calcium carbonate and is thus nonscaling. Nonscaling waters are expected to be corrosive while waters that scale are expected to be relatively less corrosive.

The LSI is not wholly satisfactory for practical prediction of the scaling and corrosion tendency. This is because it is possible for waters of varying hardness (and hence corrosivity) to have the same LSI value. The Ryznar stability index (RSI) is a modification of the LSI that overcomes this problem<sup>11</sup>:

$$RSI = 2pH_s - pH \quad [7]$$

In this scheme, an index between 6 and 7 is effectively balanced with little tendency to scale. If  $RSI < 6$ , scaling is likely (and corrosion less likely) with the scaling tendency increasing as the index decreases. For  $RSI > 7$  calcium carbonate formation probably does not lead to a protective corrosion inhibitor film and for  $RSI > 8$  mild steel corrosion is likely to become an increasing problem.

Neither the LSI nor the RSI can account for the buffering capacity of the solution. Thus, water that is high in calcium ions, but low in alkalinity and buffering capacity can have a high saturation value for calcium carbonate. Typically, the water has a large thermodynamic driving force for scale precipitation, but does not have much scaling capacity because of the low quantity of carbonate ions present. To account for these effects an alternative index was devised<sup>12</sup> that is tied to the calculated equilibrium pH rather than the measured value. The PSI index is calculated in a manner similar to the Ryznar stability index. Thus:

$$PSI = 2pH_{eq} - pH_s \quad [8]$$

where  $pH_s$  is as defined above;  $pH_{eq} = 1.465 \times \log_{10}[\text{Alkalinity}] + 4.54$ ; and  $[\text{Alkalinity}] = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-]$ . The index is interpreted in a similar manner to the RSI.

It is important to note that the above indices assume relatively dilute solutions and unit activity coefficients for dissolved species. None of the above indices can satisfactorily predict the scaling tendency of water that has significant quantities of other ions in solution, especially if they are present at high concentration. Other indices<sup>13</sup> have therefore been developed for such conditions encountered, for example, in the oil and gas industry.

There are many modern computational tools now available to determine solution speciation in a wide range of conditions. For example, **Figure 3** shows the effects of varying the calcium ion concentration, at constant total carbonate concentration, on the pH of precipitation of a calcium carbonate scale. Thus, as the water hardness (as calcium ion concentration) increases from 0.5 to 4 mM at a total carbonate of 1 mM, the pH for scale precipitation changes from

**Figure 3** Mole fraction of stable species as a function of pH for (a) 4 mM and (b) 0.5 mM  $\text{Ca}^{2+}$  concentrations at a constant total carbonate concentration of 1 mM at 298 K. Calculated with Puigdomenach, I.; Hydrochemical Equilibrium Constant Database (HYDRA/MEDUSA); Royal Institute of Technology; Stockholm. Available at [www.kemi.kth.se/medusa](http://www.kemi.kth.se/medusa).

about 8.5 to about 7.5. The domains of pH in which carbonic acid and bicarbonate ion dominate are also clearly evident.

Depending on the circumstances, calcium carbonate scale formation may be detrimental or beneficial. The detrimental effects are summarized below:

- loss of heat transfer efficiency (calcium carbonate has a low thermal conductivity), including reduced life of heat transfer surfaces because of overheating (**Figure 4**);
- loss of pipe diameter leading to reduced flow capacity or an increased pressure requirement to achieve the same flow rate;
- blockage of valves, etc.;
- reduced efficiency of detergents and soaps for washing; and
- deposits left after evaporation of water, which spoils the appearance.

Conversely divalent metal cations can act beneficially, particularly as cathodic inhibitors, for corrosion. This is because of the alkalinity at the cathode caused by oxygen or water reduction:

Thus, the local increase in hydroxide ion concentration will therefore tend to precipitate a scale, even in systems that are not intrinsically scale-forming; as is evidently shown in **Figure 3**. If the scale is sufficiently dense and nonporous, it will provide significant

**Figure 4** Carbonate scale: dense generally protective scale on a steel water pipe with some corrosion evident as general thinning: Photo courtesy of the author.

corrosion protection and, hence, the calcium ions act effectively as inhibitors. The degree of protection afforded by calcium carbonate has been studied by McCauley.<sup>14</sup> The significance of carbon dioxide in corrosion is also discussed in some detail by Simmonds.<sup>15</sup>

### 2.17.3.3 Other Inorganic Scales

Calcium carbonate is by far the most common scaling substance in natural water systems but it is by no means the only one. Thus, all dissolved species will tend to form a scale when their solubility limit is exceeded. Also, although  $\text{CaCO}_3$  is usually dominant in scales formed in potable water, waters used for other industrial purposes (e.g., heating and cooling) may form other deposits depending on the water chemistry. Indeed, many such scales comprise deposits of a range of compounds. Scales may also act to secure (adhere) other forms of fouling deposit (such as mud, silts, etc.) to a substrate.

#### 2.17.3.3.1 Silica

Silica is present in many waters; in supplied waters it can be derived from clay and similar soil types. The solubility of silica is relatively high, at least 100 ppm below pH 7, increasing to above 300 ppm at pH 10; therefore, it rarely forms a scale on its own. However, the presence of dissolved silica can promote the precipitation of silicate species, particularly magnesium silicates.<sup>16</sup>

In some more extreme conditions, for example where the supply waters are relatively high in silica, the water requires treatment to prevent scale formation. For example, fouling of heat transfer surfaces and osmosis membranes in desalination plant is problematic<sup>17</sup> and geothermal water and power supply systems tend to readily form silica scales.<sup>18</sup>

#### 2.17.3.3.2 Magnesium hydroxide and silicate

In the presence of significant dissolved magnesium ions and at high pH (typically greater than about 9–10) magnesium hydroxide may precipitate with, and participate in, overall carbonate scale formation<sup>19</sup>:

This is certainly an issue in the formation of scales from brines and marine sources, especially under cathodic protection (and is dealt with elsewhere). However, in the presence of significant dissolved

silica, which may occur in re-circulating evaporative cooling systems for example, formation of magnesium silicate may occur either directly, or by transformation of prior magnesium hydroxide.<sup>20</sup> Deposition of magnesium silicate can generally be prevented by keeping the pH less than about 8 and, more generally, by ensuring that the dissolved silica levels do not exceed 200 ppm.

#### 2.17.3.3.3 Calcium sulfate

Water containing relatively lower quantities of carbonate but a higher concentration of sulfate will tend to form a scale of calcium sulfate (gypsum:  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ;  $K_{\text{sp}} = 1.95 \times 10^{-4}$ ).<sup>21</sup> Such a water composition may occur naturally but are more commonly found in cooling towers, where acidification with sulfuric acid (to prevent calcite deposition) is used as part of the water treatment system.

In order to avoid precipitation of gypsum on heat transfer surfaces in evaporative cooling systems when using acid treatment, alternative acids could be considered (although these are more corrosive and more expensive). Alternatively, proper blow-down procedures should be used, which involve removal of part of the water from the cooling circuit with replacement with fresh make-up water. Under the correct conditions, calcium sulfate scale formation should not be a problem.

#### 2.17.3.3.4 Calcium phosphate

Phosphoric acid (or more commonly polyphosphate) is commonly added to heating and cooling waters to prevent calcium carbonate scale formation. Generally this functions not necessarily by prevention of precipitation, but by changing the nature of the precipitate such that it does not form as an adherent scale. However, scaling by calcium phosphate (which is less soluble than calcium carbonate) can occur if tricalcium phosphate ( $\text{Ca}_3(\text{PO}_4)_2$ ) is formed as its solubility product is smaller than that of calcium carbonate.<sup>22</sup>

#### 2.17.3.3.5 Iron and manganese oxides and hydroxides

Many scaling deposits may contain small quantities of dissolved iron or manganese. While the levels of these species are usually well below 200 ppb in most water supplies, occasionally higher levels may reach the customer due to corrosion and biological activity in the water supply system from iron and manganese oxidizing bacteria, giving rise to 'red' or 'black' water

quality problems.<sup>23,24</sup> However, in circulating heating and cooling systems, the iron plus manganese concentrations may reach several part per million; unless controlled, iron and manganese oxides are extremely likely to deposit within the system.

The other source of iron in heating and cooling systems is corrosion of the ferrous materials within the system. Indeed, a high level of dissolved iron is a good indicator of an ineffective inhibitor system. The most common scale in hot water systems is magnetite ( $\text{Fe}_3\text{O}_4$ ) while haematite ( $\text{Fe}_2\text{O}_3$ ) is more commonly found in cooling systems.

### 2.17.3.4 Fouling Deposits

The origins of fouling deposits are generally different in origin from scale deposits. The best way to differentiate them is that a scale deposit is a specific and important form of fouling deposit that can, to a large extent, be predicted from the water chemistry.<sup>25</sup> On the other hand, fouling is a general description of any kind of deposit that can form. It includes deposits that arise from inorganic or organic (biological) origins. Thus, in addition to scales, fouling deposits include the following:

- Sediments carried into the system with the make up water, such as silt.
- Products of reactions between the water and chemical additives.
- Insoluble corrosion products.
- Biofilms, including slimes, from bacterial, algal and other origins.

#### 2.17.3.4.1 Corrosion

Corrosion of a metal, giving rise to an insoluble corrosion product on the metal is one of the most common forms of fouling deposit. One of the main purposes of water treatment is to limit the formation of such deposits by controlling or inhibiting the corrosion process. Corrosion (i.e., anodic dissolution) can occur by any of the normal processes and therefore requires a cathodic reactant (oxidizing agent). In open water systems the cathodic reactant is dissolved oxygen while in closed systems hydrogen generation from water reduction can occur. The amount of fouling due to corrosion product formation often increases on (hot) heat transfer surfaces in response to the general increase of corrosion rate with temperature.

#### 2.17.3.4.2 Biofilms

Although natural waters are disinfected for potable (drinking) purposes, the amount of biocide (e.g.,

dissolved chlorine) present may decrease or be eliminated during service (e.g., by heating). Also, water exposed to open air will rapidly pick up all kinds of active biological material (e.g., bacteria, algae, etc.) that may have a direct or indirect effect on corrosion.<sup>26</sup>

The most common consequence of biological activity is the development of a biofilm on the metal substrate. Corrosion in the crevice formed effectively by the biofilm is possible generally by differential aeration or concentration cell mechanisms. Organisms that prefer anaerobic conditions (e.g., sulfate reducing bacteria) may preferentially colonize beneath bio-films, or other deposits, and generate local environments that are conducive to corrosion (e.g., containing sulfide species). Other bacterial organisms (acidophiles) may produce organic or inorganic (sulfuric) acids while yet other organism (e.g., algae) may respire consuming dissolved carbon dioxide and producing oxygen. If none of these issues is significant, the mere presence of an adherent biofilm will reduce heat transfer efficiency and, if it is removed by cleaning, may block valves, etc. Therefore, effective biocidal treatment is essential in both domestic and industrial settings.

### 2.17.3.5 Water Treatment

It is beyond the scope of this section to provide a detailed discussion of water treatment, however, for completeness brief comments are given below.<sup>27</sup>

#### 2.17.3.5.1 Water softening and water hardening

For many applications, calcium carbonate scaling from hard waters may be effectively inhibited by partial exchange of calcium ions with sodium ions, which is the process of cation exchange (water softening). It is important to note that softening, by reducing the scaling tendency of water and by increasing its ionic conductivity, will generally increase the corrosivity of the water. Conversely, where supply waters are extremely soft, mild water hardening is applied by use of lime (calcium hydroxide) treatment. This is especially effective for reducing the general solubility of metals in soft water supplies for domestic purposes.

#### 2.17.3.5.2 Treatment with acid

The traditional method used to control the formation of calcium carbonate scale, especially on heat transfer surfaces in evaporative cooling systems, is to add sufficient acid to create nonscaling conditions. The

carbonic acid–bicarbonate equilibrium is thereby moved in the direction of carbonic acid, which encourages loss of carbonate (as  $\text{CO}_2$ ) from the water. The most commonly used addition is that of sulfuric acid and although calcium sulfate is more soluble than calcium carbonate, as noted above, scaling of gypsum can occur. In such circumstances other acids, such as phosphoric, may be used.

#### **2.17.3.5.3 Scale inhibitors and dispersants**

Scale inhibitors/dispersants function by modifying the kinetics of nucleation and growth of the scale, although the precise mechanisms of action are still a subject of research. The most cost-effective scale inhibitors are inorganic polyphosphates (e.g., sodium hexametaphosphate); however, at higher temperatures these are subject to reversion back to orthophosphate, which is ineffective.<sup>28</sup> Organic phosphonates are also effective and more stable at higher temperatures; however, they are more costly. Organic polymers are also often very effective at inhibition of scaling by limiting nucleation and growth of the precipitated material.

#### **2.17.3.5.4 Surfactants**

Conventional cationic or anionic detergents tend to be used in heating and cooling systems in order to limit the scope of contamination of heat transfer surfaces by oils or greases and function by emulsifying the hydrocarbon contaminants. In addition, non-ionic surfactants are also useful for changing the wetting characteristics of surfaces. This can effectively reduce the tendency for fouling-type materials (silts, biomass) to deposit on surfaces.

#### **2.17.3.5.5 Corrosion inhibition in potable water systems**

Polyphosphates and silicates are suitable, at low concentrations, for use in drinking (potable) water systems for corrosion and/or scale control; they can also, in many cases limit deposition and staining from dissolved iron and manganese. Polyphosphates, used at levels from 2 to 10 ppm are particularly effective at ambient temperatures and at pH of less than 7.5 can effectively inhibit calcium scale growth. For effective corrosion control, some calcium ions in solution are required to assist in the deposition of a calcium phosphate film that limits corrosion of copper, iron and lead. Sodium silicate is less effective on its own but may be used in synergy with sodium hexametaphosphate at an optimum ratio of 4:3.<sup>29</sup>

### **2.17.4 Corrosivity of Natural Waters**

The extent to which water is corrosive (its 'corrosivity') is a function of a considerable number of interacting variables (i.e., oxygen concentration, flow rate, quantity of dissolved species, scaling tendency, etc.).<sup>30–32</sup> In view of this, it is not possible to determine the corrosivity of water for an arbitrary water composition, although it remains a future goal.

#### **2.17.4.1 pH**

The pH of natural waters is rarely outside the fairly narrow range of 4.5–8.5. Within this range, steel corrodes at approximately constant rate. The form which the corrosion takes is, however, affected by the pH. At values between 7.5 and 9.0, there is a tendency for the corrosion products to adhere as a hard crusty deposit.<sup>33,34</sup> Sometimes there are separate 'tubercles,' but these are more usually joined up to form a more or less continuous layer. Attack under the deposit is, however, usually irregular. At lower pH values, adherent corrosion products are not so evident although a very hard form of deposit is sometimes seen in pipes which have been in service for some years. Loss of pressure (due to a reduction in pipe cross section because of the development of internal corrosion product and other scales) is more commonly found in the higher pH range. In the lower pH range corrosion products may stay in suspension giving rise to 'red water' complaints. Water treatment may reduce the amount of corrosion, but if inhibition is not complete or possible, the type of attack is unaltered. For this reason, it is difficult to prevent corrosion in the pH range (4.5–8.5), as even a low degree of attack produces an adherent corrosion product which puts a barrier between the inhibitor and the metal. Grey cast iron behaves in a manner similar to steel at alkaline pH values but at low pH values it is subject to graphitization, which is the preferential dissolution of the ferrous component (graphite being an effective cathode).

Copper is affected to a marked extent by pH. In acid waters, slight corrosion occurs and the small amount of copper in solution may cause green staining of fabrics and sanitary ware. In addition deposition of copper onto aluminum or galvanized surfaces results in pitting of these metals. In most waters the critical pH is about 7.0 but in soft water containing organic acids it may be higher.<sup>35</sup> Localized pitting corrosion of copper occurs as follows: (Type I) in cold water systems where a residual carbon film is present

from the metal drawing process; (Type II) in hot water systems generally where the bicarbonate to sulfate ratio is less than one; (Type III) in cold water systems but associated with an unfavorable bicarbonate to sulfate ratio as in Type II.<sup>36</sup>

Lead is affected by carbonate content, pH value and mineral constituents.<sup>37</sup> With soft waters the simplest method of corrosion control is usually to increase the pH value by adding lime to the water. Zinc coatings on steel (galvanized) are attacked in the same way as iron, but usually more slowly.<sup>38</sup> Very alkaline waters are usually aggressive to zinc and will often remove galvanized coatings; the corrosion products consist of basic zinc carbonate or other basic compounds and may take the form of a thick creamy deposit or hard abrasive particles.

#### 2.17.4.2 Physical Processes

The effects of temperature and fluid flow are complex. The more general factors may, however, be summarized as follows<sup>39,40</sup>: (a) the velocity of corrosion reactions is greater at increased temperatures, (b) temperature changes may affect solubility of corrosion products or shift the position of such equilibria as that existing between calcium carbonate and carbon dioxide, (c) gases are less soluble at increased temperature, an effect which is, however, partly offset by greater diffusion rates and (d) modification of pH value. The overall effect is that corrosion is usually more rapid at higher temperatures, the corrosion products being often more objectionable in nature.

#### 2.17.4.3 Water Chemistry

It is of considerable interest to the water supply industry to be able to predict with certainty the corrosion rate and condition of its assets from the corrosion tendency (corrosivity) of the water. Although the Langelier index is probably the most frequently quoted measure for the corrosivity of water, it is not a very reliable guide. All that the index can do (and all that its author claimed) is to provide an indication of the thermodynamic tendency to precipitate calcium carbonate. It cannot indicate if sufficient material will be deposited to completely cover all exposed metal surfaces; consequently a very soft water can have a strongly positive index but still be corrosive. Similarly the index does not account for the physical form of the precipitate: that is, a semiamorphous 'egg-shell' like deposit can spread uniformly over all the exposed surfaces rather

than forming isolated crystals at a limited number of nucleation sites. Egg-shell type deposits have been shown to be associated with the presence of organic material which affects the growth mechanism of the calcium carbonate crystals.<sup>41</sup> Where a substantial and stable deposit is produced on a metal surface, this can be an effective anticorrosion barrier.

As well as the conventional chemical parameters generally useful in gauging the corrosivity of water, for example, pH, chloride, sulfate etc., various ratios of ions have been found to be significant for particular problems. Thus an increase in the corrosion rate of iron occurs when the chloride-to-carbonate ratio exceeds 3:1<sup>42</sup> and attack of the dezincification prone brasses arises when the chloride to carbonate hardness ratio exceeds 1:3.<sup>43</sup> More usually only very limited correlations can be made between water composition and corrosivity, and even where no multiple ion effects are involved, the response to a change in one parameter may be difficult to model mathematically, for example, the corrosion of iron which passes through a maximum between pH 7.5–8 in some natural waters.<sup>44</sup>

#### 2.17.4.4 Bacteriological Effects

The traditional understanding of the effect of biological activity is outlined in the previous section and focuses on either (a) classical differential aeration or concentration cell effects caused by a biofilmed surface, or (b) biological activity that produces a species that influences adversely the corrosion process.<sup>45</sup> The classical example is *thiobacillus ferrooxidans*, which (in the absence of oxygen) promotes solution phase oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  and consequent deposition of iron (III) oxide throughout the water system.

Recently, however, a further adverse effect of such microbial activity has been increasingly recognized. Thus, the oxidation of dissolved reduced species of iron, manganese, copper, etc., to their higher oxidation states will tend to promote pitting corrosion, particularly on passive materials such as stainless steels.<sup>46,47</sup>

<b>R<sub>a</sub></b>	A parameter that characterizes the resistance to deposition across boundary layers
<b>R<sub>c</sub></b>	Critical amount of rain required to guarantee run off
<b>R<sub>i</sub></b>	The amount of rain in a given rain event
<b>R<sub>t</sub></b>	Terrain roughness
<b>r<sub>1</sub></b>	Radius of curvature near the front of a drop
<b>r<sub>2</sub></b>	Radius of curvature near the back of a drop
<b>R<sub>s</sub></b>	The reactivity of a surface
<b>RH<sub>c</sub></b>	Relative humidity at which a surface wets
<b>T</b>	Air temperature (°K)

<b>T<sub>s</sub></b>	Temperature of the (metal) surface
<b>S<sub>i</sub></b>	Initial pollutant load
<b>S<sub>f</sub></b>	Final 'soluble' pollutant load
<b>U<sub>0</sub></b>	The approach velocity (of the air stream) at a distance <i>x</i> <sub>0</sub> , from an object
<b>u*</b>	Average friction velocity in the local boundary layer
<b>V<sub>a</sub></b>	Vapor concentration of the air
<b>V<sub>d</sub></b>	The deposition velocity of aerosols
<b>V<sub>s</sub></b>	Saturation vapor concentration
<b>β</b>	A constant used in calculating deposition efficiency
<b>ξ</b>	Mixing ratio
<b>η</b>	The capture efficiency (of aerosols) of an object
<b>θ</b>	Plate or object angle (from the horizontal)
<b>ρ<sub>p</sub></b>	The density of an aerosol (or particle) droplet
<b>μ</b>	The viscosity of air
<b>σ</b>	Surface tension (between metal surface and droplet)
<b>φ</b>	The difference in contact angle between the front and back of a drop

## 2.16.1 Typical Atmospheric Conditions

The atmosphere is the layer of gases that surround our planet Earth and that are retained by gravity. The atmosphere is not a single entity and may be divided into several regions that are subject to varying physical and chemical conditions. The lowest layer, in which 'weather' occurs, is named the troposphere and is the subject of this chapter. Above this layer, there come, in sequence, the stratosphere, the mesosphere, the thermosphere, the ionosphere, and finally the exosphere. It is the events within the troposphere that are the subject of this chapter. In this section, the typical conditions that control the formation and chemistry of gases, particulate aerosols, or rain within the atmosphere (troposphere) are outlined.

### 2.16.1.1 Atmospheric Gases

The average composition of the atmosphere and the nature of atmospheric cycles for each gaseous constituent are given in **Table 1** (from Seinfeld and Pandis<sup>1</sup>). The atmosphere is a dynamic system with its gaseous constituents being constantly exchanged by vegetation, the oceans, biological organisms, volcanic action, weathering, and human influences. For example, ozone levels are controlled by chemical processes in the upper and lower atmosphere. Methane, nitrous oxide, and carbon monoxide levels are also controlled by biological processes.

When in the atmosphere, a chemical substance may be altered either as a result of sunlight promoting the decomposition of molecules (photochemical reaction) or by chemical reactions with other substances, which can occur either homogeneously or heterogeneously. Such reactions may transform the state of a substance (gas to aerosol), allowing the substance to be removed from the atmosphere more effectively. As will be discussed later, heterogeneous reactions of ammonia and sulfur dioxide gases can lead to the formation of a range of ammonium sulfate particulates that deposit at a significantly faster rate than their gaseous precursors, dramatically affecting the course of atmospheric corrosion.

As evident in **Table 1**, the major constituents of the atmosphere are gases that are relatively inert such

as N<sub>2</sub> and O<sub>2</sub>; however, the atmosphere is an effective oxidizing medium. This is partially due to the presence of free radicals (e.g., the hydroxyl (OH) radical) and partially due to such oxidizing species as ozone (O<sub>3</sub>). Thus, many species are converted into higher chemical oxidation states, which also have an increased polarity and solubility. For example, the partially soluble SO<sub>2</sub> may be converted into SO<sub>3</sub> and then to sulfuric acid, which acidifies rainwater, particulates, and moisture films, with significant consequences for atmospheric corrosion.

The average mixing ratio referred to in **Table 1** is the average ratio of the amount (or mass) of a substance in a given volume to the total amount (or mass) of all constituents in that volume. Thus, for a particular species *i*, the volume mixing ratio is given by

$$\xi_i = C_i / C_{\text{total}} \quad [1]$$

where *C<sub>i</sub>* is the molar concentration of *i* and *C<sub>total</sub>* is the total molar concentration of air.

The mixing ratio can be readily converted to mass concentration by the following equation:

$$\text{Concentration in } \mu\text{g m}^{-3} = \xi_i \times pM_i / RT \quad [2]$$

where *M<sub>i</sub>* is the molecular weight, *p* is air pressure, *R* is the gas constant (8.314 J mol<sup>-1</sup> K<sup>-1</sup>), and *T* is temperature.

**Table 1** Atmospheric gases

Gas	Molecular weight (g)	Average mixing ratio (ppm)	Cycle
Ar	39.948	9340	No cycle
Ne	20.179	18	No cycle
Kr	83.80	1.1	No cycle
Xe	131.30	0.09	No cycle

### 2.16.1.2 Specific Atmospheric Gases

Our prime concern is with atmospheric gases that determine the interaction of moisture layers with the underlying metals through the following steps:

- Promoting the formation of moisture layers through the formation of hygroscopic particulates.
- Controlling the pH of moisture layers.
- Controlling the dissolution of oxide layers and promoting ligand exchange.

For these reasons, the key compounds are the following:

- Sulfur-containing compounds.
- Nitrogen-containing compounds.
- Strong oxidants (ozone and hydrogen peroxide).
- Organic acids.

#### 2.16.1.2.1 Sulfur-containing compounds

The principal sulfur-containing compounds in the atmosphere are  $\text{H}_2\text{S}$ , dimethyl sulfide (DMS or  $\text{CH}_3\text{SCH}_3$ ),  $\text{CS}_2$ , carbonyl sulfide (OCS), and  $\text{SO}_2$ ,<sup>2</sup> and their mixing ratios (in parts per trillion) are given in Table 2 (modified from Berresheim *et al.*<sup>2</sup>).

The primary sources of hydrogen sulfide are wetlands, plants and soils, and volcanoes. DMS is produced in oceanic waters by benthic and planktonic organisms, probably from the decomposition of dimethyl-sulfiniopropionate.<sup>3</sup> The oxidation of DMS (by OH and nitrate radicals) is a source of methane sulfonic acid and  $\text{SO}_2$  in marine atmospheres. DMS is also the prime source of sulfate cloud condensation nuclei (CCN) in marine atmospheres<sup>4</sup> and is, therefore, a direct contributor to acidified rain.  $\text{CS}_2$  is produced in oceans, wetlands, and plants and soils.<sup>2</sup>

OCS has a low reactivity and a long residence time of  $\sim 7$  years, and 7–8% of it is transported through the troposphere and into the stratosphere.<sup>5</sup> This is important, as the photolysis of OCS or reaction with O atoms leads to the widespread production of  $\text{SO}_2$  in the stratosphere that may reenter the troposphere across broad geographical zones. OCS has a number of sources including  $\text{CS}_2$  oxidation, ocean emission, and biomass burning. While the transformation of OCS to  $\text{SO}_2$  may give rise to a widespread but low level of tropospheric  $\text{SO}_2$ , the prime source of  $\text{SO}_2$  is due to industrial activity.<sup>2</sup>

The oxidation state of OCS, DMS,  $\text{CS}_2$ , and  $\text{H}_2\text{S}$  is 2, that of  $\text{SO}_4$  (and sulfate species) is 6, and that of  $\text{SO}_3$  (and sulfate species) is 6. DMS,  $\text{CS}_2$ , and  $\text{H}_2\text{S}$  are rapidly oxidized (first to sulfur dioxide and then to sulfates) and, thus, have lifetimes of a few days or

**Table 2** Average mixing ratio of a number of gases

Compound	Location	Average mixing ratio (ppt)
$\text{H}_2\text{S}$	Marine surface layer	3.6–7.5
	Coastal regions	65
	Forests	35–60
	Wetlands	450–840
	Urban areas	365
$\text{CH}_3\text{SCH}_3$	Marine surface layer	80–110
	Continental surface layer	8–60
$\text{CS}_2$	Marine surface layer	2–18
	Continental surface layer	35–120
OCS	Marine surface layer	500
	Continental surface layer	500
$\text{SO}_2$	Marine surface layer	20
	North American – clean continental	160
	Coastal Europe	260
	Polluted continental air	1500
	Urban–suburban	10–1
$\text{NO}_x$	Rural	0.2–10
	Remote tropical forest	0.02–0.08
	Remote marine	0.02–0.04
$\text{O}_3$	Urban–suburban	100–400
	Rural	50–120
	Remote tropical forest	20–40
	Remote marine	20–40

Source: Reproduced from Berresheim, H.; Wine, P. H.; Davis, D. D. Sulfur in the Atmosphere. In *Composition, Chemistry and Climate of the Atmosphere*; Singh, H. B., Ed.; Van Nostrand Reinhold: New York, 1995; pp 251–307.

less, while oxidized compounds are stable and their residence times in the atmosphere depend on the deposition rates of the liquid entities (aerosols and raindrops) in which they reside. Thus, while in terms of atmospheric corrosion the critical compounds are sulfur dioxide and sulfates, the transport and reaction of reduced sulfur compounds need to be considered. For example, DMS and OCS may be transported significant distances through the troposphere where they may be oxidized to sulfur dioxide (and other compounds) and, thus, can give rise to low but significant  $\text{SO}_2$  levels, even in isolated nonindustrial areas. Noller *et al.*<sup>6</sup> for example, found that rainwater in the Northern Territory of Australia (an isolated, non-industrial zone) was acidic at least in part because of the oxidation of DMS.

#### 2.16.1.2.2 Nitrogen-containing compounds

Key nitrogen-containing species in the atmosphere are nitrous oxide ( $\text{N}_2\text{O}$ ), nitric oxide (NO), nitrogen dioxide ( $\text{NO}_2$ ), nitric acid ( $\text{HNO}_3$ ), and ammonia

(NH<sub>3</sub>).<sup>7</sup> N<sub>2</sub>O is emitted from biological sources in soils and waters<sup>8</sup> and has a residence time of more than 50 years. It may be transformed in the stratosphere to NO, which may then transform to nitrogen dioxide, which in turn may transform to nitric acid and reenter the troposphere. Thus, both nitrogen dioxide and nitric acid can be found at significant distances from nitrogen sources. The major sources of nitrogen oxides NO<sub>x</sub> (NO + NO<sub>2</sub>) are fossil fuel combustion, soil release, and biomass burning.<sup>8</sup> **Table 2** indicates that NO<sub>x</sub> concentrations fall away dramatically from urban sources.

NH<sub>3</sub> is the primary basic gas in the atmosphere, with its major sources being animal waste, NH<sub>3</sub>-based fertilizers, and emissions from soils.<sup>9</sup> NH<sub>3</sub> is readily absorbed by surfaces (including water droplets) and therefore, its residence time is short. The concentration is highly variable (from 0.1 to 10 ppb), depending on the distance from the source. Further, ammonia may react directly with gaseous acids, as in the following equations:

or

where, the equilibrium constant is  $1 \times 10^{16} \text{ atm}^2$  and  $3.35 \times 10^{19} \text{ atm}^2$  for the formation of ammonium chloride and ammonium nitrate, respectively. Thus, as NH<sub>3</sub> is rapidly absorbed in wetted aerosols, and its product NH<sub>4</sub><sup>+</sup> readily reacts to form solids, ammonia salts are a major aerosol component.

### 2.16.1.2.3 Strong oxidants, ozone, and hydrogen peroxide

Ozone plays a major role in catalyzing the oxidation of compounds, both in the atmosphere and on surfaces. Most of the Earth's ozone is in the stratosphere; however, it may be transported into the troposphere by so-called tropopause folding events.<sup>10</sup> Ozone may also be produced by industrial activity and from the burning of fuels. As it is highly reactive, its mixing ratio can vary greatly geographically and because of diurnal cycles. Indeed, ozone may be produced by the photolysis of nitrogen dioxide during daylight hours via the following steps:

Ozone will also react with NO at night, so there is commonly a very strong diurnal cycle in ozone concentration levels. Base levels of ozone are ~20–25 ppb,

but they may rise as high as 200–400 ppb close to NO<sub>x</sub> sources.<sup>1</sup>

Hydrogen peroxide concentration is closely related to photochemical activity and has mixing ratios that range from 0.2 to 37 ppb but are centered ~2–4 ppb.<sup>11,12</sup> Hydrogen peroxide commonly forms from radical–radical reactions such as<sup>13</sup>

These radicals commonly form by oxidation of hydrocarbons; however, the radicals may also react with NO<sub>x</sub> compounds so that hydrogen peroxide levels decrease in high NO<sub>x</sub> environments.<sup>12</sup> In the gas phase, hydrogen peroxide may be destroyed by its reaction with the OH radical or by its photolysis, while in the aqueous phase it reacts with SO<sub>2</sub> (eqn [20]). Nevertheless, hydrogen peroxide is the main oxidant found in clouds, fogs, or rain.<sup>1</sup> Other oxidants that are of importance are OH<sup>•</sup> and HO<sub>2</sub><sup>•</sup>, which may be formed by oxidation of hydrocarbons.

### 2.16.1.2.4 Organic acids

The main organic acids of concern are formic acid (HCOOH) and acetic acid (CH<sub>3</sub>COOH). Such acids come from a variety of sources, including industrial activity, biogenic activity in soils, and volcanoes, but the most common source appears to be incomplete combustion. Organic acid concentrations are commonly in the 1–10 ppb range.<sup>14</sup>

### 2.16.1.3 Aqueous Phase Reactions

Prior to discussing particulate deposition and wet deposition, an understanding of aqueous phase reactions is required, as these control the chemistry and, to some extent, the formation of cloud and rain droplets, and aerosols, as well as the absorption of gases onto wet metal surfaces. The reaction of a gas with the liquid phase is controlled both by absorption and the immediate reaction of the absorbed phase, and subsequent reactions that may change the concentration of reaction products.

#### 2.16.1.3.1 Absorption and immediate reaction

It is well established that the concentration of an absorbed gas may be related to the partial pressure of the gas according to the following relationship:

$$A(\text{g}) \leftrightarrow A(\text{aq}) \quad [8]$$

$$[A(\text{aq})] = H_A p_A \quad [9]$$

where  $[A(\text{aq})]$  is the aqueous phase concentration (in

$\text{mol l}^{-1}$ ),  $p_A$  is the partial pressure in the gas phase (in atm.), and  $H_A$  is the Henry's law coefficient for species  $A$ , which is a function of temperature, as defined by Pandis and Seinfeld.<sup>15</sup> According to Seinfeld and Pandis,<sup>1</sup> species with  $H_A < 1000$  will exist mainly in the gas phase, species with coefficients between 1000 and 10 000 are considered moderately soluble in water, and those above 10 000 are considered very soluble. Henry's law coefficients for common gases are set out in Table 3 for a temperature of 298 K. While it is evident from Table 3 that many common gases would be regarded as relatively insoluble (e.g.,  $\text{SO}_2$ ,  $\text{CO}_2$ ), the absorption of these gases may be significantly increased by secondary reactions.

### 2.16.1.3.2 Secondary reactions

Dissociation and other reactions (e.g., oxidation) can decrease the concentration of dissolved species allowing further absorption. For example, absorbed  $\text{SO}_2$  may dissociate as set out below:

while:

The balance of  $\text{HSO}_3^-$  versus  $\text{SO}_3^{2-}$  depends on pH, with the former dominating at pH values of 2–7 and the latter above this. These dissociation reactions may be taken into account by defining an effective Henry's law coefficient that represents the equilibrium dissolved species when subsequent aqueous reactions are considered. The effective Henry's law coefficient for  $\text{SO}_2$  goes from  $1.23 \text{ M atm}^{-1}$  at a pH of 1 to in excess of  $10^7 \text{ M atm}^{-1}$  at a pH of 8. This has a dramatic effect on S(IV) concentrations in solution, which for a mixing

ratio of 200 ppb of  $\text{SO}_2$  at 298 K would increase from  $3 \times 10^{-7}$  to  $3 \times 10^{-3} \text{ M}$  as pH is increased from 0 to 6.<sup>1</sup>

In the case of  $\text{NH}_3$ , the Henry's law coefficient is  $62 \text{ M atm}^{-1}$  and, therefore, the gaseous species is absorbed more readily than  $\text{SO}_2$ , which then dissociates according to the following reactions:

The equilibrium constant ( $K_{\text{eq}}$ ) value for the dissociation of  $\text{NH}_3 \cdot \text{H}_2\text{O}$  is  $1.7 \times 10^{-5}$  and, thus, in solutions with  $\text{pH} < 8$ , the dissolved  $\text{NH}_3$  is predominantly in the form of ammonium ion; for  $\text{pH} < 5$  practically all the available  $\text{NH}_3$  will be dissolved in the aqueous phase. This high solubility of ammonia makes it a dominant species in industrial aerosols.

The Henry's law coefficient for  $\text{CO}_2$  absorption is  $3.4 \times 10^{-2} \text{ M atm}^{-1}$  and, therefore, its absorption would be expected to be quite low; it is indeed so under acidic conditions. The reactions are

The  $K_{\text{eq}}$  value for eqns [16] and [17] are  $4.3 \times 10^{-7}$  and  $4.7 \times 10^{-11}$  respectively, and so in basic conditions  $\text{CO}_2 \cdot \text{H}_2\text{O}$  readily dissociates to bicarbonate and hydrogen ions, allowing continued absorption of  $\text{CO}_2$ . For absorption of  $\text{CO}_2$  (at a mixing ratio of 330 ppm), the effective Henry's law coefficient rises from a value of  $3.4 \times 10^{-2} \text{ M atm}^{-1}$  at a pH of 4–1.5  $\text{M atm}^{-1}$  at a pH of 8.

### 2.16.1.3.3 Absorption of other gases

Nitric acid is extremely water soluble and would be expected to be fully dissolved in solution at all  $\text{pH} > 1$ . Although formic acid has a relatively high Henry's law coefficient, the percent dissolved in the aqueous phase will depend heavily on pH, so that for  $\text{pH} < 4$  only ~10% will be dissolved in solution, while for  $\text{pH} > 7$  almost all formic acid will be dissolved. Ozone is practically insoluble, as indicated by its very low Henry's law coefficient.

### 2.16.1.3.4 Oxidation of reduced species

In order to determine the balance between the gas phase and the absorbed phase for a number of compounds, oxidation reactions also need to be included (as noted earlier, the atmosphere is in general strongly oxidizing). A prime and important example is the absorption of  $\text{SO}_2$ , where the oxidation of  $\text{SO}_3^{2-}$  or other forms of S(IV) to  $\text{SO}_4^{2-}$  or other forms of

**Table 3** Henry's law coefficients for common gases

Species	$H \text{ (M atm}^{-1}) \text{ at 298 K}$
$\text{O}_2$	$1.3 \times 10^{-3}$
$\text{O}_3$	$1.1 \times 10^{-2}$
$\text{NO}_2$	$1.0 \times 10^{-2}$
$\text{CO}_2$	$3.4 \times 10^{-2}$
$\text{SO}_2$	1.23
$\text{NH}_3$	62
$\text{OH}$	25
$\text{HCl}$	727
$\text{HCOOH}$	$3.6 \times 10^3$
$\text{CH}_3\text{COOH}$	$8.8 \times 10^3$
$\text{NO}_3$	$2.1 \times 10^5$
$\text{HNO}_3$	$2.1 \times 10^5$

S(VI) is critical, as it allows the continued absorption of SO<sub>2</sub>, according to eqns [11] and [12].

This oxidation may occur via a variety of mechanisms, including reactions with O<sub>3</sub>, H<sub>2</sub>O<sub>2</sub>, and O<sub>2</sub> (catalyzed by Mn (II), Fe (III), and NO<sub>2</sub>), for example:

or

where S(IV) may be HSO<sub>3</sub><sup>-</sup> or SO<sub>3</sub><sup>2-</sup>, and S(VI) is HSO<sub>4</sub><sup>-</sup> or SO<sub>4</sub><sup>2-</sup>.

According to Hoffman and Calvert,<sup>16</sup> the reaction rate for eqn [19] is given by

$$1.2 \times 10^6 [\text{Fe(III)}][\text{S(IV)}] \quad [21]$$

The sulfate that forms from the oxidation of S(IV) may exist as SO<sub>4</sub><sup>2-</sup> or HSO<sub>4</sub><sup>-</sup> (H<sub>2</sub>SO<sub>4</sub> dissociates to HSO<sub>4</sub><sup>-</sup> under pH ranges likely for droplets in the atmosphere or on surfaces). The balance is governed by

The  $K_{\text{eq}}$  value for eqn [22] is  $1 \times 10^{-2}$  and thus the concentration of HSO<sub>4</sub><sup>-</sup> will increase with acidity.

Hypochlorous acid (HOCl) and hypobromous acid (HOBr) may also lead to rapid sulfur oxidation:<sup>17</sup>

The observation by a number of atmospheric corrosion scientists<sup>18–20</sup> that there is a synergistic effect among SO<sub>2</sub>, NO<sub>2</sub>, and O<sub>3</sub> gases in determining the extent of corrosion, is likely to arise, at least in part, from the role of NO<sub>2</sub> and O<sub>3</sub> in promoting the oxidation to S(VI) and, therefore, the continued absorption of SO<sub>2</sub> gas into moisture layers (be they surface moisture, rain water, or wet aerosols), as well as the acidification of these moisture layers.

### 2.16.1.3.5 Ionic reactions in the liquid phase

The ionic species formed by gaseous absorption (and subsequent oxidation reactions) may combine to form ionic solids that can act as nuclei for cloud drops or aerosol particles. Further, ammonium chloride and ammonium nitrate may form as a direct consequence of gaseous reactions, as detailed in eqns [3] and [4]. The stability of the different solids will depend on the liquid concentration of the various species and pH. Typical reactions and their equilibrium constants

are given below:

### 2.16.1.4 Analysis of Typical Systems

While some of the basic reactions governing gas/aqueous phase interactions are set out in eqns [25]–[28], a rigorous analysis requires the evaluation of the chemical potentials of the gas, liquid, and solid phases as a function of concentration, temperature, and pressure, and the effect of droplet geometry on these factors. This level of detail is outside the scope of this chapter and therefore, the results from detailed analyses of three systems representing industrial and urban environments particularly relevant to atmospheric corrosion are presented, as follows:

- Industrial environment containing H<sub>2</sub>SO<sub>4</sub>, NH<sub>3</sub>, and water vapor
- Urban environment containing HNO<sub>3</sub>, NH<sub>3</sub>, and water vapor
- A mixed industrial/urban environment containing H<sub>2</sub>SO<sub>4</sub>, NH<sub>3</sub>, HNO<sub>3</sub>, and water vapor.

#### 2.16.1.4.1 Sulfuric acid–ammonia–water systems

In this section, we follow the approach of Seinfeld *et al.*<sup>1,21</sup> and consider a system containing gaseous H<sub>2</sub>SO<sub>4</sub>, NH<sub>3</sub>, and water. Aerosols will nucleate homogeneously or heterogeneously and, because of their high solubility, both H<sub>2</sub>SO<sub>4</sub> and NH<sub>3</sub> will be readily absorbed; they will react according to eqns [13], [14], and [28] to form a series of solid and dissolved species, including ((NH<sub>4</sub>)<sub>3</sub>H(SO<sub>4</sub>)<sub>2</sub>), (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, NH<sub>4</sub>HSO<sub>4</sub>, NH<sub>4</sub><sup>+</sup>, SO<sub>4</sub><sup>2-</sup>, HSO<sub>4</sub><sup>-</sup>, and NH<sub>3</sub>(aq). This system is of prime importance in determining the chemistry of aerosols in industrial locations. Figure 1 (from Seinfeld and Pandis<sup>21</sup>) illustrates this behavior at low RH (30%) and at a H<sub>2</sub>SO<sub>4</sub> concentration of 10 μg m<sup>-3</sup>.

At low ammonia levels, the aerosols consist primarily of H<sub>2</sub>SO<sub>4</sub>, with some NH<sub>4</sub>HSO<sub>4</sub>(s) and significant water (H<sub>2</sub>SO<sub>4</sub> attracts a significant amount of water even at low RH).<sup>21</sup> When the ammonia/sulfuric acid ratio increases above a molar ratio of

**Figure 1** Aerosol composition for a system containing  $10 \mu\text{g m}^{-3}$   $\text{H}_2\text{SO}_4$  at 30% RH and  $T = 298 \text{ K}$  as a function of the total (gas plus aerosol) concentration. Reproduced from Seinfeld, J.; Pandis, S. *Atmospheric Chemistry and Physics: From Air Pollution to Climate Change*; Wiley Interscience: New York, 1997.

0.5,  $\text{NH}_4\text{HSO}_4(\text{s})$  becomes the dominant species, and  $\text{H}_2\text{SO}_4$  and associated water levels fall to zero.<sup>21</sup> As the molar ratio approaches 1, the salt letovicite  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2(\text{s})$  forms and gradually replaces  $\text{NH}_4\text{HSO}_4(\text{s})$ . At a molar ratio of 1.25–1.5,  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2(\text{s})$  goes from being the dominant to the sole species and at molar ratios from 1.5 to 2 ammonium sulfate salts form. At molar ratios of 2 or greater, ammonium sulfate salt is the sole species.<sup>15</sup>

At 75% RH, the results are very different; the system is affected by the deliquescence of  $\text{NH}_4\text{HSO}_4$  (which has a deliquescent relative humidity (DRH) of 40%) and  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$  (DRH = 69%), and so is in general a solution of  $\text{NH}_4^+$  and a sulfate species (whose form depends on ammonia levels). Thus, the aerosol is a liquid solution of  $\text{H}_2\text{SO}_4$  at low ammonia levels,  $\text{HSO}_4^-$  at moderate ammonia levels, and  $\text{SO}_4^{2-}$  at

ammonia/sulfate ratios above 1.5, while the solid  $(\text{NH}_4)_2\text{SO}_4$  forms at ratios above 2 when there is sufficient ammonia to completely neutralize the sulfate.<sup>21</sup>

It is evident from the above discussion that the composition and hydrogen ion concentration within a wet aerosol will depend critically on the relative balance of  $\text{H}_2\text{SO}_4$  and  $\text{NH}_3$  in the atmosphere. The hydrogen ion concentration will determine the extent of oxide dissolution promoted by the deposition of the aerosol and thus the extent of corrosion. This result can be generalized to environmental systems containing a range of S-containing gases and ammonia, and it emphasizes the need for an understanding of both acid and alkali precursors in understanding the corrosiveness of an environment.

#### 2.16.1.4.2 Ammonia–nitric acid–water systems

According to Seinfeld and Pandis,<sup>1</sup> ammonia and nitric acid readily react in the atmosphere to form  $\text{NH}_4\text{NO}_3$  (eqn [4]). This may either occur homogeneously or, if the ambient RH is lower than the DRH of  $\text{NH}_4\text{NO}_3$  (62%), it may occur heterogeneously, with  $\text{HNO}_3$  being readily absorbed in wet aerosols ( $H_A = 2.1 \times 10^5 \text{ M atm}^{-1}$ ). If the RH is above the DRH of  $\text{NH}_4\text{NO}_3$ , the compound may dissociate:

However, the equilibrium dissociation constant of  $\text{NH}_4\text{NO}_3$  is highly dependant on temperature and so, for typical atmospheric levels of ammonia and nitrate, almost all of the species will be in the gas phase above  $30^\circ\text{C}$ , while at temperatures approaching  $0^\circ\text{C}$  most of the available species will be solid (below the DRH).<sup>1</sup> Therefore, in urban atmospheres that are low in sulfates but high in acid solutions, ammonium nitrate particulate will readily form.

#### 2.16.1.4.3 Ammonia–nitric acid–sulfuric acid–water systems

This type of environment reflects a typical industrial/urban atmosphere that contains  $\text{NH}_3$ ,  $\text{HNO}_3$ ,  $\text{H}_2\text{SO}_4$ , and water vapor. According to Seinfeld and Pandis<sup>1</sup> a range of solid phases ( $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{HSO}_4$ ,  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$ ,  $\text{NH}_4\text{NO}_3$ ) and aqueous phases ( $\text{NH}_4^+$ ,  $\text{H}^+$ ,  $\text{HSO}_4^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ) can exist.

In situations where there is insufficient ammonia to neutralize the sulfate, the sulfate will tend to drive the nitrate to the gas phase and will tend to exist as bisulfate (or  $\text{NH}_4\text{HSO}_4$  if ambient RH is below the DRH of this salt).<sup>1</sup> In ammonia-rich solutions there is competition between sulfate and nitrate for the

available ammonia, which results in a reduction in the formation of ammonia sulfate aerosol compared to systems free of nitric acid.<sup>1</sup>

The three cases discussed above highlight under what conditions different compounds in aerosols will form and what aqueous species will exist; they highlight, in particular, the roles of ammonia in neutralizing acid aerosols and nitrates in replacing sulfate aerosol formation. The same factors will also determine the chemistry of cloud nuclei and raindrops. It is apparent that to obtain an accurate understanding of aerosol (or raindrops) formation and chemistry, a full knowledge of gas species is required. From the 1980s onward, a significant body of experimental work<sup>18–20</sup> was carried out on defining the effects of various gas dosages on atmospheric corrosion. Most of these dose functions were on the basis of SO<sub>2</sub> levels, although some<sup>19,20</sup> incorporated the effects of oxidants (such as O<sub>3</sub>). Unfortunately, no consensus was reached as to the appropriate dose function to use, possibly because the exposure regimes incorporated different levels of other gases (e.g., nitrates, ammonia). These earlier studies might have been of more value if the gas regimes at each exposure site had been studied in more depth and a refined characterization scheme developed.

### 2.16.1.5 Reactions in Salt Aerosols

Marine aerosols may react with a range of gaseous species to form products such as ammonium chloride, sodium nitrate, sodium sulfate, and sodium bisulfate; for example, H<sub>2</sub>SO<sub>4</sub>(g) may be absorbed into an aerosol, and it may react with NaCl. This reaction may permit H<sub>2</sub>SO<sub>4</sub> (or other strong acids such as HNO<sub>3</sub> that have lower vapor pressures relative to HCl) to accumulate in the aerosol, increasing acidity, and causing HCl to volatilize<sup>22</sup>:

or

Alternatively, in urban environments HNO<sub>3</sub>(g) may react with marine aerosols:

Thus, gaseous HCl may enter the atmosphere through the dechlorination of airborne sea salt particles; however, as HCl is relatively soluble ( $H_A = 727$ ), it is

readily reabsorbed into atmospheric water droplets. In turn, these HCl-rich droplets may then react with and promote the absorption of other strong acids:

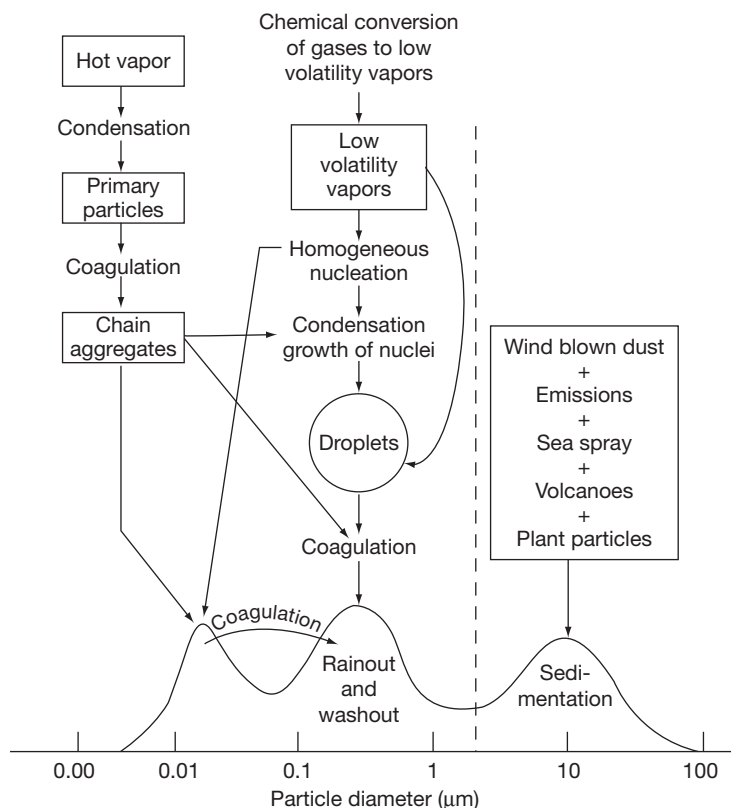

Such cycling of HCl can thus lead to significant acidification of both aerosols and rain or cloud droplets in marine locations<sup>23</sup> with significant contamination by industrial or urban pollutants. The extent of chloride depletion is evident in the work of Keene *et al.*<sup>24</sup> who looked at the Na/Cl ratio of rainwater (the majority of Na and Cl in rain water will be derived from the scavenging of marine aerosol) as a function of distance from the nearest coast in Australia. They found that the ratio moved from close to 0.8 (the expected ratio of seawater) to up to 1.3, at 500 km from the coast, which implies that chloride loss in marine aerosols may be up to 40%.

### 2.16.1.6 Aerosols

Aerosols or particles in the atmosphere may either be emitted from a source directly as particles (primary aerosol) or be formed in the atmosphere by gas-to-particle conversion processes.<sup>1</sup> Primary aerosols may arise from natural sources such as soil dust, sea salt, biological debris, and volcanic dust, or from anthropogenic sources such as industrial dust and soot from fuels or biomass combustion.<sup>8</sup> Of these, soil dust and sea salt are the major sources. Aerosols range in size from tens of angstroms to several hundred micrometers and, as shown in Figure 2,<sup>25</sup> can be divided into two classes: fine particles (<2.5 μm) and coarse particles (>2.5 μm). In general, coarse particles other than water droplets correspond to the primary aerosols and fine particles correspond to the secondary aerosols. Coarse and fine particles are transformed and removed from the atmosphere separately and so they can be treated independently.

As evident in Figure 2, fine particles are divided into two modes – nuclei mode and accumulation mode – the nuclei mode of particles, being from the condensation of gases, grow by coagulation, while the accumulation range of particles largely form from coagulation of the nuclei mode and by condensation of vapors onto existing particles. Typically, the accumulation particles outnumber the coarse particles by three orders of magnitude or more and have up to ten times the surface area.<sup>26</sup> However, the deposition rate of the accumulation particles is two orders of

**Figure 2** Idealized schematic of the distribution of aerosol size ranges and sources. Reproduced from Whitby, K. T.; Cantrell, B. Fine Particles. In Proceedings of the International Conference on Environmental Sensing and Assessment, Las Vegas, NV, 1976; Institute of Electrical and Electronic Engineers.

magnitude less than that of coarse particles; therefore, they would be expected to deposit on surfaces at similar rates (see [Section 2.16.3.1.2](#)).

The compositions of fine and coarse aerosols are reasonably distinct, reflecting their diverse origins. Fine aerosols commonly contain sulfate, ammonia, and organic and elemental carbon, while coarse aerosols contain sea salt, dust (silicon, calcium, magnesium, aluminum, and iron), and biogenic organic particles (pollen spores and plant fragments).<sup>27</sup> Nitric acid reacts with both aerosol fractions (according to eqns [4] and [32]) and thus nitrates are found in both size fractions.<sup>27</sup> Thus, the chemistry of the accumulation mode is influenced by the sulfuric acid and ammonia systems described above, while the coarse mode is influenced by the absorption of sulfuric and nitric acids into the marine aerosol.

Both coarse and fine aerosols may be hygroscopic and can absorb water from the atmosphere. The DRH values for common aerosol constituents are given in [Table 4](#).<sup>28,29</sup> The DRH is the RH at which a solid aerosol will absorb enough water to become a

saturated aqueous solution. Further increasing the RH will lead to additional condensation of water into the aerosol. DRH is dependent on temperature and for aerosols with more than one component, it is in general significantly less than that of the more wettable salt. Considering some marine and industrial aerosols, the DRH of a mixture of  $\text{NaNO}_3$  and  $\text{NaCl}$  (which may occur if  $\text{HNO}_3$  is absorbed into a marine aerosol) is 71.3%, while that of a mixture of  $\text{NH}_4\text{NO}_3$  and  $(\text{NH}_4)_2\text{SO}_4$  is 52.3%.<sup>30</sup> When wetted salts are dried, there is often a very strong hysteresis in recrystallization, so that recrystallization may occur at RH levels significantly below the DRH.

Wetted aerosols may also absorb organic molecules, with some studies<sup>31</sup> indicating that these may form an outer surface layer (with the polar part of the molecule in the aqueous solution and the nonpolar in air). The formation of such coatings may dramatically restrict evaporation from the aerosols.

**Table 4** DRH of common aerosols (at 20 °C)

Salt	DRH (%)
Na <sub>2</sub> SO <sub>4</sub>	84.2
NH <sub>4</sub> Cl	80.0
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	79.9
NaCl	75.3
NaNO <sub>3</sub>	74.3
(NH <sub>4</sub> ) <sub>3</sub> H(SO <sub>4</sub> ) <sub>2</sub>	69.0
NH <sub>4</sub> NO <sub>3</sub>	61.8
NaHSO <sub>4</sub>	52.0
(NH <sub>4</sub> )HSO <sub>4</sub>	40.0
MgCl <sub>2</sub>	35.0

### 2.16.1.6.1 Marine aerosol production

Salt aerosols may be generated either by the ocean or from surf, via bursting bubbles generated by ocean whitecaps (breaking waves that generate white foam).<sup>32</sup> particles torn from the crests of ocean whitecaps,<sup>33</sup> or breakers on the shore.<sup>34</sup> Surf waves tend to produce coarse aerosols, while ocean activity produces medium sized aerosols.<sup>35</sup> Thus, the magnitude of aerosol production from the ocean largely depends on the extent of whitecap coverage, which is related to latitude. Equatorial regions have low whitecap coverage and regions at high latitudes have high whitecap coverage.<sup>33</sup> Salt production from surf is dependant on local winds,<sup>34</sup> but may also depend on the seabed profile close to the shore (with steep slopes and mud flats reducing aerosol production).<sup>36</sup> An additional factor that may affect both ocean and surf wave heights (and thus aerosol production) is 'fetch.' To reach their maximum height, waves require a significant length of water where wind can blow across them. This length is defined as the fetch, and if fetch is below a critical value, waves will not reach their maximum height<sup>37</sup> and salt production will be reduced. Along a coast, islands, capes, and other features may reduce the fetch distance.

The implications of these aerosol production dynamics are significant. First, salt production and, thereby, salt deposition and marine aerosol-induced corrosion would be expected to be lower in tropical compared to temperate latitudes. Second, salt production from shallow or relatively narrow bays (<300 km) will be reduced and so will salt deposition and marine aerosol-induced corrosion. Experimental studies by Cole *et al.*<sup>38,39</sup> have demonstrated both the latitude and bay effects on salt production.

### 2.16.1.6.2 Types of aerosol

The nature of aerosols clearly depends on location. In marine and industrial locations, aerosols occur in both the coarse and the fine modes, with the fine mode being dominant adjacent to particular sources (e.g., highways) but falling rapidly with distance from the source.<sup>1</sup> The fine mode is dominated by sulfates, nitrates, and ammonia with the exact chemistry controlled by the processes outlined in **Sections 2.16.2.4.1–2.16.2.4.3**. The coarse mode consists of particles of soil dust, sea salt, fly ash, and particles generated by mechanical wear such as tire wear particles. Aerosol fractions are often derived from particles of less than 1 µm (PM<sub>1</sub>) or 10 µm (PM<sub>10</sub>) in diameter. Typical mass values<sup>1</sup> of PM<sub>1</sub> and PM<sub>10</sub> are 30–150 and 100–300 µg m<sup>−3</sup> for urban locations.

The definition of the acidity of aerosol is quite complex. Three measures are often used, the pH of the aerosols (sometimes referred to as the *in situ* free acidity in aqueous aerosols), strong acidity and free acidity. Strong acidity is the total [H<sup>+</sup>] derived when the collected aerosol is dissolved in an excess of water (nmol H<sup>+</sup> per m<sup>3</sup> of air) while free acidity is the [H<sup>+</sup>] concentration of collected aerosols (without dissolution in water). The pH of aerosols depends heavily on the RH as it controls the aqueous content of the aerosol and, thereby, the concentration of ions. In sulfate containing aerosols, the strong acidity includes H<sup>+</sup> released by bisulfate dissociation which is not included in free acidity. The immediate reaction of an aerosol with a surface would be most affected by the pH of the aerosol; however, the overall impact of the environment on the surface as a whole would be affected by the strong acidity.

Pathak *et al.*<sup>40</sup> looked at the acidity of aerosols in the PM<sub>2.5</sub> range collected in Hong Kong. These aerosols were rich in ammonia and sulfate with their composition controlled by the NH<sub>4</sub><sup>+</sup>:SO<sub>4</sub><sup>2−</sup> ratio which controls the neutralization of acid sulfate (as outlined in **Section 2.16.2.4.1**). A differentiation was made between samples collected when the wind blew off the ocean and that when it blew off the land. Land derived aerosols were ammonia-rich and marine derived aerosols were ammonia poor. Thus, the continental aerosol had a higher strong acidity than the marine derived aerosol (62 vs. 35 nmol H<sup>+</sup> per m<sup>3</sup> of air). However, the free acidity was higher for the marine aerosol (because of the higher water fraction in the marine aerosol). There was a very wide range in pH from −0.62 to 2.35 for all aerosols, with the pH

increasing as the RH and the ammonia: sulfate ratio increased.

Other studies have shown similar low pH values in urban locations. Yao *et al.*<sup>41</sup> found that in Hong Kong the fine aerosol primarily consisted of  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  in a ratio of 0.7 which is consistent with letovicite ( $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$ ) and had an estimated pH from  $-1$  to  $1.5$ . Takeuchi *et al.*<sup>42</sup> sampled aerosol from an urban site in Yokohama, Japan and found that the major constituents of the aerosol were  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{NO}_3^-$ , with some  $\text{Na}^+$  and  $\text{Cl}^-$ , while the average aerosol pH was estimated to be between  $2$  and  $2.2$ . Some chemical and pH differentiation occurred as a function of size, with the  $\text{PM}_{10}$  aerosol having a slightly lower pH ( $1.9$ – $2.1$ ) and higher concentration of sulfate relative to the  $\text{PM}_2$  fraction (pH  $2$ – $3$ ).  $\text{NH}_4\text{Cl}$  and  $\text{NH}_4\text{NO}_3$  are the major ammonia species reflecting processes that occur in a  $\text{NO}_2$  rich environment (see Section 2.16.2.4.3).

In a marine location, the coarse fraction dominates (typical  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$  ranges are  $1$ – $4$  and  $10$   $\mu\text{g m}^{-3}$ , respectively) and is associated with marine aerosols. Keene *et al.*<sup>23</sup> found that in the air over the ocean, in addition to the coarse fraction, there were also submicron sulfur-containing aerosols. Freshly ejected aerosol will have a pH similar to that of seawater ( $\sim 8$ ), which will rise as the aerosol evaporates and equilibrates with the environment, increasing the ionic concentration. In fact according to Sander and Crutzen<sup>43</sup> the concentration of ions in seawater and marine aerosol (at a RH of  $76.2\%$ ) are respectively  $[\text{Cl}^-]$ ,  $0.55$  and  $5.4$  M,  $[\text{HCO}_3^-]$ ,  $2.3 \times 10^{-3}$  and  $2.7 \times 10^{-2}$  M, for seawater pH of  $8.7$  and an aerosol pH of  $9.5$ . The aerosol pH was calculated for a RH of  $76.2\%$  assuming the solution was saturated with chloride and  $\text{HCO}_3^-$  was in equilibrium with the gas phase. Subsequently, the pH may change as a result of aqueous phase reactions (particularly the absorption of  $\text{H}_2\text{SO}_4$ ) and volatilization of the products of these reactions (e.g.,  $\text{HCl}$ ).<sup>44</sup> Models developed by Chameides and Stelson<sup>45</sup> indicate that the original alkaline pH may be reduced to below  $5$  within  $15$  min. The submicron S-containing aerosols will be primarily formed by the condensation of  $\text{H}_2\text{SO}_4$  in clean environments, or by the absorption of  $\text{H}_2\text{SO}_4$  by fine particulates in polluted environments. Subsequently, these wet aerosols may absorb other gases, including ammonia, which will lead to particle neutralization, so that submicron aerosols in marine locations will have a mixture of  $\text{H}_2\text{SO}_4$ ,  $\text{NH}_4\text{HSO}_4$ ,  $(\text{NH}_4)_2\text{SO}_4$ , and  $\text{NH}_4\text{NO}_3$ .<sup>46</sup>

Historically, there has been considerable variation in the estimated pH of marine aerosols. Recent

work by Keene *et al.*<sup>47</sup> measured the pH of the larger sea-salt fractions (geometric mean diameter (GMD)  $\geq 2.9$   $\mu\text{m}$ ) and found that the median pH ranged from  $3.1$  to  $3.4$ , while the median pH for submicron fractions was  $\leq 1.6$ . This was supported by previous work<sup>48</sup> on marine aerosols off Bermuda, where pH values of aerosols were found to vary from  $0$  to  $4$ – $5$  ( $1.3$   $\mu\text{m}$  aerosols had a pH of  $2$ ,  $2.4$   $\mu\text{m}$   $\sim 3$ , and  $11$   $\mu\text{m}$   $\sim 4.6$ ). It is notable that the pH of these aerosols was strongly buffered by bisulfate. Similar results were found for aerosols measured off New England, although even the coarsest aerosols (GMD  $\geq 10$   $\mu\text{m}$ ) exhibited pH values less than  $4$ . Acidified marine aerosols may be particularly corrosive as the acid component may promote oxide dissolution, while the chloride will attack a metal surface.

Ocean-produced aerosols will have residence times of hours to days and, therefore, could be rendered acidic by gaseous reactions. In contrast, most surf-produced aerosols (see Section 2.16.2) will be deposited within the first few hundred meters of a coast and within minutes of their production, and therefore, there may be insufficient time for enough gaseous absorption to render them acidic.

In rural locations, the coarse aerosol fraction is dominant (typically  $\text{PM}_{10}$  varies from  $2.5$  to  $8$  and  $\text{PM}_{2.5}$  from  $10$  to  $40$ ) and aerosols are of natural sources but with a small anthropogenic source.<sup>49</sup> In remote continental<sup>50</sup> locations, the coarse fraction dominates (typically  $\text{PM}_{10}$  varies from  $0.5$  to  $2.5$  and  $\text{PM}_{2.5}$  from  $2$  to  $10$ ) with source of particles being natural sources such as dust, pollen, plant waxes, or the products of atmospheric oxidation processes outlined in Section 2.16.1.3.

### 2.16.1.7 Cloud Nucleation and Rain Chemistry

Cloud nucleation occurs when aerosols undergo rapid growth in the presence of a supersaturation of water vapor. These aerosols are called CCN. The supersaturation of water arises because of the steady decrease in temperature with distance from the ground, so that when a hot mass of air rises, the RH of the air steadily increases (or alternatively the saturation vapor pressure decreases). CCN will tend to be the larger sized aerosols (from coarse aerosols into the accumulation mode). Once cloud droplets have formed, they may continue to grow by scavenging the remaining aerosols in the clouds or by coalescence. Once a cloud droplet reaches a critical size and falls as rain, it may continue to scavenge aerosols or absorb

gases (as detailed in previous sections) until it reaches the ground.

Because of the processes detailed previously, considerable concentrations of ionic species can build up in rainwater. Typically observed concentrations of the major species are given in Figure 3.<sup>14</sup> However, the formation and deposition of rain drops occur over significant time and spatial scales so that the composition of rainwater will reflect pollutant levels in a general area and not only at the point of deposition. Fog arises when CCN form and grow close to the ground. A number of studies have identified the problem of acid fog, both within cities and in rural and forested areas in their vicinity. North American studies of fog water have indicated pH levels from 2.9<sup>51</sup> to 3.6<sup>52</sup> with high nitrate, ammonia, and sulfate levels.

The variation of chloride concentration in rainwater, shown diametrically in Figure 3 shows a strong dependence on the distance from the location where the rainwater was sampled. Keywood *et al.*<sup>24</sup> have

shown that chloride concentration falls in an approximately exponential fashion, with peak values between 500 and 1000  $\mu\text{eq l}^{-1}$  at the coast,  $\sim 10 \mu\text{eq l}^{-1}$  at 500 km from the coast, and less than  $1 \mu\text{eq l}^{-1}$  in the center of the Australian continent. Given that the prime source of chloride in rainwater is the scavenging of marine aerosols, it is not surprising that they found that the factors that control aerosol concentration (sea state, rainfall) also influenced chloride concentration in rain water.

In Table 5, typical rainwater chemistry and pH values from locations around the globe are given. While there is a tendency for rainwater in or near industrial or urban areas to have low pH values, some industrial sites have relatively high pH values. In the mid-1980s<sup>66</sup> lower pH values were reported (pH of 4.2–4.7) close to the industrial belt in central and eastern Europe. The relatively moderate pH values reported in such industrial centers as Nanjing (China), Dhanbad (India) or Mugla (Turkey) are

associated with the neutralizing role of ammonia and the alkali metals (particularly  $\text{Ca}^+$ ), despite the high sulfate and nitrate contents of rain water. In urban areas, such as Mt Rokko in Japan, ammonia may play a significant neutralizing role, while nitrate levels tend to be equal in importance to sulfates.

Surprisingly, acid rainwater and cloud droplets have been found in areas remote from any industrial activity. Charlson *et al.*<sup>67</sup> proposed that the concentration of CCN may be controlled by DMS emissions from phytoplankton. Gillet and Ayers<sup>61</sup> found that DMS may indeed promote the formation of acid CCN (pH 4.8–5.8) in Tasmania, a largely rural island off the south-east coast of Australia. The same workers<sup>64</sup> also found acidic cloud droplets (average pH 3.8) and rainwater (average pH 4.9) in a number of inland sites in the remote Northern Territory of Australia. This acidity could be attributed to sulfates from DMS decomposition (the decomposition of DMS is complex, but may be triggered by OH radicals or NO) and to formate and acetate in cloud water and rainwater. Rainwater chemistry in rural and remote areas may also be influenced by the transport of particulate and gaseous matter. Work by Schwartz<sup>68</sup> indicates that industry-produced acids may be deposited up to 1000 km from their source. This is confirmed by Poste *et al.*,<sup>62</sup> who studied rainwater and fog acidity at two locations in northern New South Wales ~200 and 500 km from any industrial location, and ~40 and 60 km from the coast, respectively. Both sites exhibited high levels of salts of marine origin and significant sulfates from anthropogenic sources. Rainwater and fog water had similar compositions, but fog water was more concentrated (by a factor of 3).

### 2.16.1.8 Redox Potential and pH Diagrams

Graedel and Frankenthal,<sup>69</sup> on the basis of the evidence of Graedel<sup>70</sup> and Garrels,<sup>71</sup> have proposed distribution of potential and pH for dew rain water and fog. Garrels also proposed redox–pH ranges for ‘environments in contact with the atmosphere.’ Graedels and Frankenthals<sup>69</sup> and Garrels<sup>71</sup> distributions along with the potential–pH variations for the redox couples representing the stability of water, hydrogen peroxide, and the reduction of oxygen and ozone are given in [Figure 4](#).

Line A and line B enclose the stability region of water; line A representing

and line B representing

Line C and line D enclose the stability region of hydrogen peroxide; line C representing

and line D representing

Line E is the variation in potential for the reduction of oxygen

and line F is the variation in potential for the reduction of ozone

The similarity of Garrels<sup>71</sup> and Graedel<sup>70</sup> analyses with the  $\text{H}_2\text{O}_2$  stability boundary (eqn [37]) implies that natural waters behave as if they contain a small amount of dissolved oxygen. It is notable that ‘waters’ not in contact with oxygen such as ground water lose their oxidizing potential.<sup>71</sup> If the redox potential of dew/rain/aerosols is primarily controlled by the oxidizing species present, those with high ozone content would be expected to have higher potentials than predicted by Graedel and Frankenthal.<sup>69</sup>

## 2.16.2 Transport of Gases and Aerosols

### 2.16.2.1 General Scale of Movement of Gases and Particles

In the atmosphere, a series of processes occur in parallel – gaseous species, aerosols, and drops are constantly reacting, while the air is in constant motion on scales of a centimeter or less (tiny eddies) to continental dimensions. At the same time, species are entering the atmosphere from a variety of natural and man-made sources, or are leaving the atmosphere through scavenging by raindrops or by impact with the ground or ground-based objects. The period during which a species stays in the atmosphere is referred to as its residence time (which is closely related to the reactivity of the species) and residence time is closely related to the distance the species may travel from its source. In [Figure 5](#), the temporal scales (residence times) and spatial scales are plotted for a range of chemical species.<sup>1</sup> As the OH radical (formed by photolysis of  $\text{O}_3$  and  $\text{H}_2\text{O}_2$ ) is highly

**Figure 4** Redox diagram. Adopted from Pourbaix, M. *Atlas of Electrochemical Equilibria in Aqueous Solutions*, 2nd English Edition; National Association of Corrosion Engineers: 1440 South Creek Drive, Houston Texas 7704, 1974; Graedel, T. E.; Frankenthal, R. P. *J. Electrochem. Soc.* **1990**, 137, 2385–2394.; Garrels, R. M. *Mineral Equilibria at Low Temperature and Pressure*; Harper: New York, 1960. MW represents mine waters, R represents rain waters, S represents streams, and Q represents normal ocean water.

reactive, it has a residence time of less than 0.01 s, and it will travel not more than centimeters from its source. In contrast,  $\text{N}_2\text{O}$  has lifetimes in tens of years, and it will be mixed throughout the global atmosphere (the major pathway for  $\text{N}_2\text{O}$  loss is photodissociation in the stratosphere).

The spatial impact of a species may be increased by its reaction with other species. For example, DMS has a residence time of a few hours and would not be expected to move more than several hundreds of meters from its source, yet as outlined earlier<sup>64</sup> the acidification of cloud droplets and raindrops at inland locations was attributed in part to DMS. As indicated earlier, the decomposition of DMS may produce both  $\text{SO}_2$  and  $\text{H}_2\text{SO}_4$ . The residence time of  $\text{SO}_2$  is significantly greater (days rather than hours) and subsequently its dispersal from source will be greater

(kilometers rather than hundreds of meters). Finally, both gaseous  $\text{SO}_2$  and  $\text{H}_2\text{SO}_4$  are readily absorbed in aerosols that may have residence times of months and which can be dispersed distances ranging from tens to hundreds of kilometers from their source, depending on size. Such aerosols can then either form CCN or be scavenged by either these nuclei or by raindrops and thus acidification of cloud droplets or rain may occur at a significant distance from the original source of DMS.

Figure 5, therefore, has significant implications for atmospheric corrosion, as it highlights that highly reactive species such as hydroxide radicals will travel extremely short distances, oxidants such as  $\text{NO}_x$  and  $\text{H}_2\text{O}_2$  limited distance (although tropospheric  $\text{O}_3$  may travel further), gaseous  $\text{SO}_2$  short distances, and aerosols will travel moderate distances from

**Figure 5** Spatial and temporal scales of variability for atmospheric constituents. Reproduced from Seinfeld, J.; Pandis, S. *Atmospheric Chemistry and Physics: From Air Pollution to Climate Change*; Wiley Interscience: New York, 1997.

their source. Thus, direct impacts of gaseous species on metallic corrosion will be limited to tens of kilometers from source, while indirect effects via aerosols or rain deposition may be at appreciable distances from source.

### 2.16.2.2 Transportation Processes

More detailed studies of transport have been undertaken either by using an analytical approach (Eulerian or Lagrangian) or by a numerical approach (using computational fluid dynamics (CFD)). In this section, the movement of gaseous species will be illustrated using the analytical approach and that of aerosols using the numerical approach.

#### 2.16.2.2.1 Analytical approach to gas transport

The transport of gases in a turbulent fluid can be modeled<sup>1</sup> using a Gaussian distribution, with the plume equation having the form below when evaluated along the centerline ( $y=0$ ) and at ground ( $z=0$ ).

$$\langle c(x, 0, 0) \rangle = q / (\pi u \sigma_y \sigma_z) \times \exp(-b^2 / 2\sigma_z^2) \quad [41]$$

where  $q$  is the mean concentration from a point source,  $u$  is the wind speed,  $x$  is distance from the source,  $b$  is the effective source height, and  $\sigma_y^2, \sigma_z^2$  are the Gaussian variances.

This equation has a maximum value for some intermediate value of  $x$  and of wind speed. The position of this maximum depends on the stability class of the plume, that is, A (extremely unstable), B (moderately unstable), C (slightly unstable), D (neutral), E (slightly stable), and F (moderately stable). Also, two case scenarios exist – that when the plume has not reached its maximum height and that when it has.<sup>1</sup>

The critical downward distance at which the surface concentration is at a maximum is given in **Figures 6 and 7** (from Seinfeld and Pandis<sup>1</sup>) as a function of source height and plume stability.

It is evident from **Figures 6 and 7** that for low-height sources ( $<10$  m) such as short stacks, the maximum pollutant levels will occur at 100–500 m of the source, while for plumes emitted from sources at a height of 100 m the maxima may occur up to 10 km from the source.

Thus, gaseous pollutants may directly impact on metal structures for distances up to tens of kilometers from their source. However, they may also be absorbed in aerosols and transported significantly greater distances.

#### 2.16.2.2.2 Aerosol transport

The corrosion science literature has concentrated on the transport of marine aerosols and within corrosion science there has been little work on the deposition of

**Figure 6** Critical downwind distance  $x_c$  as a function of source height  $h_s$ , and stability class for a plume that has reached its final height. Reproduced from Seinfeld, J.; Pandis, S. *Atmospheric Chemistry and Physics: From Air Pollution to Climate Change*; Wiley Interscience: New York, 1997.

**Figure 7** Critical downwind distance  $x_c$  as a function of source height  $h_s$ , and stability class for a plume that has not yet reached its final height. Seinfeld, J.; Pandis, S. *Atmospheric Chemistry and Physics: From Air Pollution to Climate Change*; Wiley Interscience: New York, 1997.

industrial aerosols, which, as outlined previously, are significantly finer (generally  $<2.5 \mu\text{m}$  diameter). The factors influencing the transport of marine aerosols will also influence industrial aerosols, but industrial aerosols would be less affected by the various deposition processes and would, therefore, have significantly larger residence times, and would be transported longer distances.

Ohba *et al.*<sup>72</sup> proposed that aerosols should be divided into categories: salt produced on the shoreline, which is relatively coarse and whose

concentration showed an exponential decrease with distance from the coast; and salt produced at sea, which is finer and whose concentration showed a slower decrease tending towards an asymptotic value that is relatively constant. Other works<sup>73–79</sup> have confirmed this double dependence of aerosol concentration on distance from the coast and have also shown that aerosol concentration depends on wind strength and direction and, in particular, on the strength and frequency of winds arising over oceans.

Cole *et al.*<sup>80</sup> developed a CFD model of marine aerosol transport. Aerosols are convected by wind, lifted by diffusion, and dragged down by gravity. Gravity depends on aerosol mass and, therefore, diameter, with the wet particle diameter being critically dependant on local RH for salt produced by the sea, but not for salt generated at the shoreline which has had insufficient evaporation time to reach equilibrium with the local RH. Salt is removed from the atmosphere by both wet (rainout and washout) and dry deposition. In rainout, salt aerosols become the nuclei of raindrops that agglomerate and fall to earth (thus, there is insignificant aerosol above the cloud layer). Washout refers to the scavenging of salt aerosols by raindrops and its effectiveness depends on the radius of the aerosol droplet. Dry deposition includes deposition on sloping as well as horizontal surfaces. Trees are particularly effective at scavenging salt from the atmosphere, as too are man-made structures. While medium to large aerosols will be readily trapped, small salt aerosols will follow the air-streams around tree leaves and man-made structures. Therefore, separate models are run for the coarse surf-produced aerosols and the relatively fine ocean-produced aerosols.

**Figure 8** (from Cole *et al.*<sup>80</sup>) shows the effect of wind speed on the salt concentration ( $\% \text{ volume} \times 10^{10}$ ) with distance from the coast for surf-produced aerosols (ground roughness 0.5 m) at a height of 2.0 m above ground level. **Figure 9** (from Cole *et al.*<sup>80</sup>) shows the effect of wind speed on the transport of salt produced in the open ocean over a distance of 50 km from the coast at a height of 2.0 m above ground level (ground roughness 0.5 m, ground RH 70%, rainfall  $1200 \text{ mm year}^{-1}$ ). **Figure 10** (from Cole *et al.*<sup>80</sup>) shows the effect of ground roughness on the salt concentration of surf-produced aerosols (ground roughness does not appear to have a significant effect on the transport of ocean-produced aerosols). **Table 6** gives some typical roughness values of various terrain types (from AS/NZ 1170).

**Figure 8** Effect of wind speed on salt concentration with distance from coast of surf-produced aerosols. Note that this excludes ocean-produced aerosols. Cole, I. S.; Chan, W. Y.; Trinidad, G. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2004**, 39(1), 89–96.

**Figure 9** Effect of wind speed on salt concentration with distance from coast for ocean-produced salt. Reproduced from Cole, I. S.; Chan, W. Y.; Trinidad, G. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2004**, 39(1), 89–96.

Rainfall also has a significant influence on the transport of ocean-produced aerosols. For example, given a wind speed of  $7.5 \text{ m s}^{-1}$ , a ground roughness of  $0.5 \text{ m}$  and  $70\% \text{ RH}$  at a distance of  $200 \text{ km}$  from the coast, uniform rainfalls of  $200$  and  $1600 \text{ mm year}^{-1}$  will reduce aerosol concentrations by  $3\%$  and  $23\%$  respectively, relative to the case of no rain. The effect of  $\text{RH}$  is even more marked. This can be illustrated from the ratios of the aerosol concentration when the surface  $\text{RH}$  is  $20\%$ ,  $70\%$ , and  $90\%$  to that when it is  $50\%$ , which are  $1.4$ ,  $0.5$ , and  $0.2$  respectively (under the same conditions as above).

The strong effect of humidity on salt concentration is related to two effects. The first arises as the model assumes (following Seinfeld and Pandis)<sup>1</sup> that there is a linear decrease in temperature with height and thus a corresponding increase in  $\text{RH}$ ; therefore,

the surface  $\text{RH}$  controls the cloud height. The cloud height is the upper limit for salt aerosol dispersion (aerosols act as scavengers or are scavenged by CCN); therefore, the higher the cloud level, the greater the vertical dispersion of salt and the greater the residence time and transport of the average aerosol. The second effect is on the particle size (or mass). The main constituents of marine aerosols are  $\text{NaCl}$  and  $\text{MgCl}_2$ , with each salt wetting at  $75\%$  and  $35\% \text{ RH}$  (at  $20^\circ\text{C}$ ) respectively, so that above these humidities the aerosol increases its mass, leading to a higher terminal velocity and a greater sink effect of gravity. As the major mass change occurs after the wetting of the  $\text{NaCl}$  constituent, a significant decrease in transport is observed when the surface  $\text{RH}$  is increased from  $50$  to  $70\%$  (recall that the  $\text{RH}$  at a height will be greater than that at the surface). This model has been validated by experimental studies of aerosol deposition across Australia.<sup>38</sup> Experimental and numerical studies indicate that while coarse surf-produced aerosols are deposited close to the coast, those ocean-produced aerosols that have a diameter less than  $2.5 \mu\text{m}$  can be transported significant distances (hundreds of kilometers) from the coast. As industrial aerosols tend to be finer than marine aerosols, it is probable that these too will be transported significant distances from their sources.

## 2.16.3 Deposition

### 2.16.3.1 Forms of Deposition

Traditionally, deposition onto surfaces has been classified as wet or dry deposition, with deposition by rain and snow being defined as wet deposition, and deposition by particulates and aerosols (even when these are wet) being defined as dry. Deposition modes can also be defined as follows:

- Deposition of snow, rain, or fog.
- Deposition of particulates or aerosols.
- Deposition of gases into wet surfaces.
- Depositions of gases onto dry surfaces.

#### 2.16.3.1.1 Rain

Raindrops are generally assumed to have a  $100\%$  efficiency of deposition onto a surface. However, once a raindrop falls onto a surface, it may splash off the surface and break into smaller drops, which could reenter the airflow and not redeposit. Analyses by Cole and Paterson<sup>81</sup> indicated that although splash does occur, it does not lead to significant loss

**Figure 10** Effect of ground roughness on salt concentration for surf-produced aerosols. Cole, I. S.; Chan, W. Y.; Trinidad, G. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2004**, 39(1), 89–96.

**Table 6** Typical roughness values (from AS/NZ 1170)

Roughness (m)	Terrain	Roughness (m)	Terrain
2	City buildings (10–30 m)	0.2	Level wooded country; suburban buildings
1	Forests	0.06	Isolated trees, long grass
0.8	High-density metropolitan	0.02	Uncut grass, airfields
0.4	Center of small towns	0.008	Cut grass

of deposition efficiency for rain falling onto stationary objects. However, it can be quite significant for fast-moving objects (e.g., airplanes in flight).

### 2.16.3.1.2 Gas and particle deposition

Similar principles can be applied to both the dry deposition of gases and to the deposition of particles. A generic formulation, common in atmospheric physics, but pioneered in corrosion studies by Haynie,<sup>82,83</sup> and developed by Spence *et al.*,<sup>84</sup> is given by

$$D = CV_d \quad [42]$$

where  $V_d$  is the deposition velocity, and  $C$  is the upstream concentration of depositing species. If  $C$  is measured in  $\text{kg m}^{-3}$ ,  $D$  is measured in  $\text{kg m}^{-2} \text{s}^{-1}$ , and therefore,  $D$  is multiplied by the surface area to get the total deposition.

There are a number of approaches to defining the deposition velocity. One approach, developed for atmospheric corrosion by Spence *et al.*,<sup>84</sup> is the resistance factor approach, where the deposition velocity can be expressed as follows:

$$V_d = 1/(R_a + R_s) \quad [43]$$

where  $R_a$  characterizes the deposition across boundary layers to the surface, and  $R_s$  characterizes the reactivity of the surfaces. If  $R_s$  is low, the value of  $R_a$  determines  $V_d$ .  $V_d$  is determined from an analogy with momentum transport, which gives

$$V_d = u_*^2/U \quad [44]$$

where  $U$  is the upstream velocity, and  $u$  is the average ‘friction velocity’ in the local boundary layer.  $u_*^2$  is proportional to the local turbulent kinetic energy in the boundary layer and thus depends on the size of the obstacle. This approach recognizes the importance of air turbulence, but assumes that the turbulence is generated solely by flow over the obstacle, ignoring the effect of turbulence in the air upstream of the obstacle. Given that  $R_s$  is taken as zero, the work of Spence *et al.*,<sup>84</sup> and Haynie<sup>83</sup> leads to a dependence of deposition velocity on wind speed, where

$$V_d \propto U^n \quad [45]$$

Here the value of the exponent  $n$  varies from 0.6 to 0.7 for sheets and 0.5 for panels and wire.

A more recent approach is that of Klassen and Roberge<sup>85</sup> who considered the effect of inertial

impaction and turbulent diffusion and introduced the following equation for application to CLIMAT units and salt candles:

$$D = CU\eta \quad [46]$$

where  $\eta$  is the capture efficiency of the target. This is multiplied by the projected target area to get the total deposition. This approach implicitly includes turbulence due to the target, but also assumes that there is no upstream turbulence.

In summary, all approaches presented above assume smooth flow upstream of the objects, which effectively mean that they are treating objects isolated from the surrounding environment. In the real environment, upstream turbulence due to ground roughness will vary significantly and may have a major impact on deposition onto salt candles, plates, or buildings.

A variation to the resistance approach is that of Cole *et al.*,<sup>86</sup> in which the overall deposition velocity  $v$  can be calculated from the deposition velocities for the individual deposition mechanisms. A mechanism may act in parallel or in series and when the mechanisms occur together or in parallel (at the same distance from the surface), the deposition velocities can simply be added together:

$$v = \sum_i v_i \quad [47]$$

If the deposition mechanisms occur in different layers and the depositing aerosol must pass through all layers (act in series), deposition velocities must match between layers:

$$v_i = v_j \quad [48]$$

The main deposition mechanisms for aerosol particles are the following:

- Gravitational settling.
- Turbulent diffusion.
- Laminar diffusion (also called Brownian deposition and diffusiophoresis).
- Thermophoresis (migration from high temperatures to low).
- Electrostatic attraction.
- Momentum-dominated impact.
- Vortex shedding (transport by transient laminar flows).
- Filtering (flow past or through raised fabrics).
- Photophoresis (motion generated by an intense beam of light).

However, while all these mechanisms can be important in interior spaces, in open spaces the prime mechanisms

are gravity, momentum-dominated impact, and turbulent diffusion. **Figure 11** compares the efficiency of deposition of particles of increasing sizes onto a cylinder (typical of a salt candle, as described in ISO 9205) via momentum-dominated impact and turbulent diffusion. Efficiency is defined as the percentage of aerosol flux that would pass through the air space in the absence of an object. For very small particles, smaller than 0.1 or 0.01  $\mu\text{m}$  in diameter, electrostatic attraction and laminar diffusion play a significant role in deposition. For small particles with a diameter of  $\sim 1 \mu\text{m}$ , turbulent diffusion dominates, while for larger particles with a diameter of  $\sim 5 \mu\text{m}$  momentum-dominated impact dominates. For particles with a diameter above 20  $\mu\text{m}$  gravitational settling becomes the prime deposition mechanism. As the particle diameter increases past 2.5  $\mu\text{m}$  the deposition efficiency increases dramatically.

An approximate equation for the deposition velocity for momentum dominated impact is<sup>86</sup> as follows:

$$v_i = -x_0/\tau + \sqrt{(x_0/\tau)^2 + U_0^2} \quad [49]$$

where  $U_0$  is the approach velocity at distance  $x_0$  from the object. If  $U_0$  is the upstream velocity,  $x_0$  is of similar

**Figure 11** Influences of momentum-dominated impact and turbulent diffusion on the deposition of aerosols onto a cylinder of arbitrary diameter at arbitrary wind speed, as a percentage of the aerosol flux that would pass through in the absence of the cylinder. The percent turbulence is the turbulence intensity (rms velocity/mean velocity) upstream. The reference diameter is the particle diameter for which 50% of particles are deposited by momentum-dominated impact. For a salt candle the reference diameter is 40 microns. Reproduced from Cole, I. S.; Paterson, D. A.; Lau, D. Holistic Modeling of Gas and Aerosol Deposition and The Degradation of Cultural Objects. In *Physical Techniques in the Study of Art, Archaeology and Cultural Heritage*, to be published by Elsevier, 2007.

size to the object diameter. The relaxation time  $\tau$  is given by

$$\tau = \frac{D_p^2 \rho_p C_c}{18\mu} \quad [50]$$

with particle diameter  $D_p$ , density  $\rho_p$ , air viscosity  $\mu$ , and Cunningham slip correction factor  $C_c$ .

In fact, Cole *et al.*<sup>87</sup> found that if the deposition modes are combined, the deposition onto common objects (plates, salt candles) in the open environment can be estimated by a formula analogous to that of Klassen and Roberge<sup>85</sup>:

$$D = CVA\eta \quad [51]$$

where

$$\eta = 100 \times I^\beta \times C_s \quad [52]$$

and  $I$  is turbulence;  $\beta$  is a constant (determined numerically to be 0.38), and  $C_s$  is the shape factor.

The shape factor, as well as the deposition efficiency, is reasonably robust, being reasonably independent of wind speed; however, it does show a dependency on particle size. In **Table 7** (from Cole *et al.*<sup>87</sup>), deposition efficiencies are given for particles in the size range 1–229  $\mu\text{m}$  for salt candles and exposure plates (at 45° to the airflow). It is apparent that deposition onto salt candles is less efficient than onto exposure plates for small and medium size particles (<21  $\mu\text{m}$  diameter). For large particles (>21  $\mu\text{m}$  diameter), the efficiency of deposition onto salt candles is marginally higher than that onto exposure plates.

In practical terms, this implies that in severe marine locations where large aerosols will make up a large fraction of the aerosol distribution, it is reasonable to assume that the deposition onto an exposure plate will be approximately the same as that onto a salt candle. However, in milder locations the aerosol distribution will be dominated by aerosols of less than 15  $\mu\text{m}$  and so the salt candle measurements of deposition will be ~71% of that on exposure plates.

The average shape factors for particles (assuming the particle distribution given by Fitzgerald<sup>35</sup> of <20  $\mu\text{m}$  for plates and salt candles are given in **Table 8** (from Cole *et al.*<sup>87</sup>). These factors can be used in conjunction with eqn [48] to calculate deposition efficiencies and thus deposition rates. Deposition also depends on turbulence, which in turn depends on the upstream roughness of the terrain. However, the latter dependence is relatively weak

**Table 7** Comparison of salt deposition efficiency on plate and salt candle

Particle diameter ( $\mu\text{m}$ )	Percentage deposition (%)		
	Salt candle	Plate	Ratio
1	9.2	12.2	1.33
6	7.6	12.2	1.61

and can be approximated by

$$I = 0.069 + 0.5R_t \quad [53]$$

where  $R_t$  is terrain roughness.

Thus, as roughness increases from 0.06 to 0.4 m, the deposition efficiency onto a salt candle of aerosols of 20  $\mu\text{m}$  diameter increases from 20% to 30%. Typical values of terrain roughness are 0.06 m for isolated trees and long grass, and 0.4 m for the center of small towns.

This model of deposition onto simple objects can be extended to more complex objects such as buildings or rows of buildings. The deposition onto an isolated building (10 m high and 20 × 20 m in plan) was computed using CFD and the result is given in **Figure 12** (from Cole *et al.*<sup>87</sup>). The randomness in **Figure 12** is caused by the stochastic nature of the simulation. The aerosol deposition rate is lowest near the ground, high near the upper edge of the front face and on the sides, and is highest on the upper corners and upper sides. The deposition rate is highly influenced by local wind turbulence, which is highest on corners and sides. **Table 9** (from Cole *et al.*<sup>87</sup>) gives the average deposition rates for particles of varying diameter onto a building compared to deposition of

the same sized particles onto a salt candle. It is apparent that the average deposition rate onto a building face is less than half that on a salt candle, although deposition onto the edges of a building could be up to twice that on a salt candle.

In **Figure 13** (from Cole *et al.*<sup>87</sup>), the calculated deposition onto a row of 2D buildings is shown (the buildings were 3.32 m high, 12.5 m wide and were spaced 30 m apart). The plot demonstrates the rapid fall-off in deposition with increasing number of houses. Such a fall-off was observed experimentally and is reported in Cole *et al.*<sup>39</sup> The data presented in **Figure 13** has been transformed to derive a theoretical urban facade factor, so that the deposition onto the facade of a dwelling close to the coast in an urban (low-rise) setting would be only 23% of the deposition onto an equivalent facade of a dwelling where there were no dwellings between this dwelling and the coast.

The above examples have been calculated for marine aerosols; however, similar effects would also occur for industrial aerosols, although the exact magnitude of the effects would be dependent on particle size.

### 2.16.3.1.3 Deposition of gases onto wet and dry surfaces

In estimating both the wet and dry deposition of gases onto surfaces, it can be assumed that the gas concentration near the surface approximates the local composition and that any absorbed gas is readily replaced. The absorption of gases into moisture layers on metal surfaces is governed by the same factors that control absorption of gases into aerosols (outlined in **Section 2.16.1.3**) and will in part be controlled by the Henry's law coefficient. In contrast, the surface absorption of gaseous species onto dry surfaces is controlled by normalized reactivity. **Table 10** (from Seinfeld and Pandis<sup>1</sup>) presents the effective  $H_a$  and the normalized reactivity values for various gas species.

**Figure 13** Results from CFD modeling of deposition onto a row of houses. Reproduced from Cole, I. S.; Lau, D.; Chan, F.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2004**, 39d(4), 333–338.

The effective  $H_a$  in Table 10 takes into account reactions of the aqueous species. When  $H_a$  is high and the normalized reactivity is low (e.g., sulfur dioxide), deposition will be primarily through absorption into a moisture droplet (be it a wet aerosol or a surface moisture film). When  $H_a$  is low and the normalized reactivity is high (ozone), direct gaseous absorption onto dry surfaces will dominate. Table 10 indicates that those species of prime importance to atmospheric corrosion (ammonia, sulfur dioxide, formic acid, and acetic acid) will all primarily be absorbed through the moisture layer. Of the nitrogen species, nitric acid will be readily absorbed into the moisture layer, while nitrogen dioxide will undergo limited interactions with both a dry and a wet surface. While the oxidizing catalyst  $O_3$  and hydrogen peroxide will be readily absorbed on a dry surface their residence times in the atmosphere are extremely short and, therefore, the source would have to be very close to the metal surface for the concentrations of these gases to be significant. Thus for practical purposes, gaseous deposition onto a dry surface is of marginal importance to atmospheric corrosion.

### 2.16.3.2 Comparison of Deposition Modes

The relative significance of particulate deposition and gaseous deposition in an industrial environment clearly depends on the particulate and gas concentrations (aerosol deposition will dominate in marine environments). However, a comparison of deposition modes in given typical compositions is useful. Consider the deposition onto a plate exposed at an angle of  $45^\circ$  in an exterior environment where the total concentration of particulates is  $20 \mu\text{g m}^{-3}$  (dry weight), which may be ammonium sulfate, ammonium bisulfate, or hydrogen sulfate, while the wind speed is  $3 \text{ m s}^{-1}$  and gaseous concentrations are  $\text{CO}_2$  at 400 ppm,  $\text{SO}_2$  at 75 ppb,  $\text{NH}_3$  at 20 ppb,  $\text{O}_3$  at 200 ppb, and  $\text{H}_2\text{O}_2$  at 10 ppb.

Work by Sehmel<sup>88</sup> indicates that ammonium sulfate particles typically have a bimodal size distribution with peaks at  $\sim 0.7$  and  $3 \mu\text{m}$ , with the smaller particles having three times the concentration (by volume) of the coarse particles. For this exercise, let us simplify the distribution and assume that the mass of fine particles ( $0.7 \mu\text{m}$  diameter) is  $15 \mu\text{g m}^{-3}$  and the mass of coarse particles ( $3 \mu\text{m}$  diameter) is  $5 \mu\text{g m}^{-3}$ .

Deposition of particles traveling horizontally will be dominant and will be defined by eqn [46]. Sehmel<sup>88</sup> indicates that typical efficiencies for 0.7 and  $3 \mu\text{m}$  particles would be  $\sim 0.26\%$  and  $18\%$ , and thus the flux at a typical wind speed of  $3 \text{ m s}^{-1}$  will be  $0.12$  and  $2.7 \mu\text{g m}^{-2} \text{ s}^{-1}$  for the fine and coarse particles, respectively. This then gives a deposition rate per hour of  $10$  to  $150 \mu\text{g m}^{-2}$  or  $108 \mu\text{g/dry weight per hour}$  onto a plate of size  $100 \times 150 \text{ mm}$  at an angle of  $45^\circ$  to the vertical.

If this amount of particulate were to deposit into a moisture film, it would then change the composition of that film to an extent that depends on the particulate composition and thickness of the moisture film. The change in  $[\text{H}^+]$  and  $[\text{SO}_4^{2-}]$  in  $\text{M l}^{-1}$  per hour is given in Table 11.

Modeling by Cole *et al.*<sup>89</sup> estimated that for the gaseous compositions given above, the aqueous phase concentrations will be  $1.7 \times 10^{-6} \text{ M}$  of  $[\text{H}^+]$  and  $1.2 \times 10^{-4} \text{ M}$  of  $[\text{SO}_4^{2-}]$ , or  $0.63 \times 10^{-4} \text{ M}$  of  $[\text{H}^+]$  and  $0.34 \times 10^{-4} \text{ M}$  of  $[\text{SO}_4^{2-}]$  in the absence of  $\text{NH}_3$ . Thus, the deposition of particulate onto a moisture film will substantially increase the ionic content and acidity of the film. If the moisture film persists for a number of hours, particulate deposition is likely to dominate over gaseous absorption.

A second comparison can be made between the hydrogen ion flux to the surface of a similar metal sample from acidified rain and from particulates. In Figure 14, the 'free' hydrogen ion flux per day onto a metal surface is estimated from  $(\text{NH}_4)_3\text{H}$

**Table 11** Effect of particulates on moisture film composition

Particulate concentration ( $\mu\text{g m}^{-3}$ dry weight)	Particulate type	Moisture film thickness ( $\mu\text{m}$ )	$[\text{H}^+]$ (M)	$[\text{SO}_4^{2-}]$ (M)
20	$(\text{NH}_4)_2\text{SO}_4$	100	—	$7.5 \times 10^{-4}$
20	$(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$	100	$4 \times 10^{-4}$	$8 \times 10^{-4}$
20	$\text{NH}_4\text{HSO}_4$	100	$8.5 \times 10^{-4}$	$8.5 \times 10^{-4}$
20	$\text{H}_2\text{SO}_4$	100	$20 \times 10^{-4}$	$10 \times 10^{-4}$
20	$(\text{NH}_4)_2\text{SO}_4$	500	—	$1.5 \times 10^{-4}$
20	$(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$	500	$0.8 \times 10^{-4}$	$1.6 \times 10^{-4}$
20	$\text{NH}_4\text{HSO}_4$	500	$1.7 \times 10^{-4}$	$1.7 \times 10^{-4}$
20	$\text{H}_2\text{SO}_4$	500	$4.0 \times 10^{-4}$	$2.0 \times 10^{-4}$
5	$\text{H}_2\text{SO}_4$	500	$1 \times 10^{-4}$	$0.4 \times 10^{-4}$

**Figure 14** Hydrogen flux onto a metal surface by particle deposition and rain deposition.

( $\text{SO}_4$ )<sub>2</sub> and  $\text{H}_2\text{SO}_4$ , assuming that the particulate dissociates on the surface in accordance with standard equilibrium constants. This is compared to the free hydrogen ion flux from rain water, assuming an unbuffered solution for a daily rainfall of 5 and 50 mm. It is apparent that fluxes are of similar orders of magnitude, but acidified rain is the major source of  $\text{H}^+$  if the rain water pH is low and rainfall high, while particulate deposition is of prime importance if the rainfall is low and the concentration of acidified particulates is high.

The analysis indicates that while dry deposition of gases onto metal surfaces is likely to be of marginal importance, rain deposition, particulate deposition, and gaseous absorption into moisture films are all likely to be significant sources of both acidity and ion concentration in moisture on metal surfaces in industrial environments. The evaporation of moisture layers formed and enriched by the processes above will lead to the precipitation of a range of ionic compounds (many of which are listed in Table 4). Being hygroscopic, these compounds will promote further wetting if they remain on the surface. The next two sections discuss the cleaning, retention, and wetting of these salts on metal surfaces.

## 2.16.4 Role of Rain and Wind in Surface Cleaning

The products that accumulate on a surface control future hygroscopic wetting and the nature of the moisture films that develop. Surfaces may be cleaned by either rain or wind; however, the effectiveness of these processes is highly dependent on both the characteristics of the wind and rain, and the state of the surface, as discussed below.

### 2.16.4.1 Role of Rain in Surface Cleaning

In this section, a simple model for the movement of raindrops, and thus their ability to clean a 'fresh' surface, is developed. In this context, a fresh surface refers to a surface that remains relatively impervious to moisture (i.e., not a porous surface that absorbs moisture). According to Cole *et al.*,<sup>81</sup> during rain, drops will grow on the surface as they coalesce and absorb impacting droplets until they reach a critical size, above which they begin to move. At the critical size, the gravitational force directed along the plate ( $gM \sin \theta$ ) is balanced by the shear force at the base of the drop ( $\tau A$ ) and a force due to surface tension. The shear force tends to zero when the drop is not moving. For the force due to surface tension, let  $2\phi$  be the difference in interfacial contact angle between the front and the back of the drop. Then, for a drop of radius  $r$ , the radii of curvature near the front and back of the drop ( $r_1$  and  $r_2$  respectively) are roughly given by  $r_1/r = r/r_2 = 1 - \tan \phi$ . The difference in pressure within the drop between the front and back extremities of a drop is then

$$p_1 - p_2 = \sigma/r_1 - \sigma/r_2 \quad [54]$$

If the drop is not moving and the gravitational force is balanced by the surface tension, this pressure difference is hydrostatic and is given as follows:

$$p_1 - p_2 = 2\rho g r \sin \theta \quad [55]$$

By combining eqn [54] and [55], a relationship can be derived for the maximum radius of a stationary drop in terms of the plate angle and the difference in interfacial angle:

$$r^2 = \frac{\sigma}{2\rho g \sin \theta} \left[ \frac{1}{1 - \tan \phi} - (1 - \tan \phi) \right] \quad [56]$$

For air and water  $g = 9.81 \text{ m s}^{-2}$ ,  $\rho = 1000 \text{ kg m}^{-3}$ , and  $\sigma = 0.07275 \text{ Pa m}$ .

A diagram of the maximum drop radius as a function of plate angle and difference in interfacial contact angle is given in Figure 15 (from Cole *et al.*<sup>81</sup>). It is apparent that both the plate angle and the difference in interfacial angle are of prime importance in determining the critical size. In particular, it is notable that the stable drop size increases dramatically as  $\phi$  approaches  $45^\circ$ .

The concept of single-drop movement has been embedded in a more complex model of drop movement, created using a fluid dynamics passage in which 71 million droplets were deposited as simulated rain

**Figure 15** Variation of maximum stable drop size with  $\phi$ , where  $2\phi$  is the difference in interfacial contact angle between the front and the back of the drop; at five plate orientations ( $\theta = 5^\circ$  to  $90^\circ$ ). Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng.. Sci. Technol.* **2007**, 42(2), 91–104.

onto a  $2 \times 2$  m surface and their subsequent movement down the surface was studied.<sup>44</sup>

During the studies,<sup>81</sup> drops on the surface grew by absorbing raindrops impacting on them and by merging with other drops. When drops rolled off the surface, the water they left behind was more than made up for by the collection of smaller drops on the way down. As each drop grew, it rolled faster and so it is reasonable to assume that once a drop reaches a critical size it will remove itself from a surface. Overall, it was observed that over time, the amount of water on the surface built up to a peak and then tended to release at once, giving periods of almost no runoff followed by periods of strong runoff. This is shown in the stepped shape of the pollution level curve in **Figure 16** (from Cole *et al.*<sup>81</sup>). In the experiments,<sup>81</sup> 0.0157 mm of water was deposited per timestep and therefore, the duration of a timestep depended on the simulated rain intensity. Loss of water through evaporation and substrate porosity was not included. The pollutant was assumed to have the solubility of sea salt.

The significance of **Figure 16** can be illustrated with regard to ‘average’ rainstorms in the Australian cities of Adelaide and Darwin, which are chosen as they span the rain intensity variation across mainland Australia, having 4.6 and 28.8 mm h<sup>-1</sup> respectively as average rainfall intensities for a one-hour rain shower with a one-month recurrence interval. Therefore, the average shower timesteps in Adelaide and Darwin would be 13 and 2 s respectively. As shown in **Figure 16**, there is a factor of 10 decrease in soluble pollutant levels on the surface between timesteps 80 and 120. By timestep

**Figure 16** Pollution levels on the rain-washed part of the surface, together with a fitted exponential decay rate based on simulations of 71 million droplets depositing on a  $2 \times 2$  m surface. Each timestep represents the deposition of 0.0157 mm of water. Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng.. Sci. Technol.* **2007**, 42(2), 91–104.

200 (representing 43 min in Adelaide and 6.7 min in Darwin), the amount of pollution left was <1% of the initial value.<sup>81</sup> This only applies to soluble pollutants.

To the first order, the effect of rain on cleaning a fresh plate can be approximated by<sup>81</sup>

$$S_f = S_i \times e^{-\alpha R} \text{ if } R_i - R_c > 0 \quad [57]$$

or

$$S_f = S_i \text{ if } R_i - R_c < 0 \quad [58]$$

where  $S_f$  and  $S_i$  are the final and initial ‘soluble’ pollutant load, respectively,  $R_i$  is the amount of rain (in mm) in a particular rain shower or event, and  $R_c$  is the critical amount of rain required to guarantee runoff and thus cleaning. The value of  $R_c$  depends on drop size, surface parameters (e.g., surface energy), and plate slope, and can be estimated from an analysis such as that presented in **Figure 16**; for conditions relevant to the data set defined above, it can be approximated by  $r/2$  (where  $r$  is the maximum radius of a stationary drop). Experimental studies<sup>87</sup> have verified this formulation and value of  $R_c$ .

#### 2.16.4.2 Removal of Salts by Wind

While in theory the removal of salts by wind could be significant, in practice it is only significant in climates where rain is very limited or when the wind carries abrasive material. In wind tunnel tests, Muster and Cole<sup>90</sup> found that significant amounts of salt were removed only when wind speeds were  $\geq 9$  m s<sup>-1</sup> and RH was  $\leq 40\%$ . These wind speeds represent <10% of the year in Australian cities. Work by Cole *et al.*<sup>87</sup> is in agreement with these results in the case where salts

were dry when deposited, but demonstrated that if salts were wet when deposited, wind speeds of up to  $14 \text{ m s}^{-1}$  did not remove such salt particles. In the case where salt is deposited as a wet aerosol onto reactive surfaces (steel, zinc, aluminum–zinc), the aerosol reacts with the surface as it evaporates and forms a reaction product that binds the crystallized salt to the surface.

#### 2.16.4.3 Transfer of Pollutants in Raindrops to a Surface

This section is concerned with defining the conditions where raindrops will evaporate on a metal surface, leaving precipitated pollutants. In tests where stainless steel, galvanized steel, and zinc plates were exposed to marine environments for periods of 2–24 h, Cole *et al.*<sup>91</sup> observed fine-scale crystals with compositions indicative of marine origin and with geometries consistent with deposition in raindrops. If raindrops are to evaporate, they must not be removed either by the motion of other drops (total rainfall must be less than  $R_c$  defined previously) or by their own motion. If the drop radius is less than that given by eqn [56], stationary drops will not begin to move; however, raindrops will maintain some of their preimpact velocity after contacting the metal surface. For such moving drops, the critical factor is whether they will evaporate before they roll off the metal surface. Work by Cole *et al.*<sup>87</sup> indicates that this is a function of the hydrophilic or hydrophobic nature of the surface and of course the distance they have to travel to roll off the plate. For strongly hydrophilic and strongly hydrophobic surfaces, the difference in interfacial angle ( $2\phi$ ) is small and so drops will tend to roll off in both cases. The presence of corrosion products on a surface can increase  $\phi$ . For example, all but the finest drops ( $<10 \mu\text{l}$ ) will run off an exposure plate (typical dimensions  $150 \times 150 \text{ mm}$  at an angle of  $45^\circ$ ), while quite large drops (up to  $36 \mu\text{l}$ ) may evaporate on an exposed roof (dimensions  $3 \times 3 \text{ m}$ ,  $30^\circ$  angle) on a summer day. This again indicates the difference between exposure plates and actual structures. The residue of raindrops observed by Cole *et al.*<sup>91</sup> might be associated with light rain and fine raindrops.

These studies, on the effectiveness of rain in cleaning surfaces and the nature of rain that can evaporate on a surface, highlight the fact that rain-drop size and rainfall intensity are critical factors in determining the impact of rain on pollutant levels on metal surfaces. In general, locations closer to the

equator will have more intense rain with larger raindrops, which will be more effective in cleaning surfaces, while locations at high or low latitudes will have less intense rain with smaller raindrops, which will be less effective in cleaning surfaces and may in fact evaporate on metal surfaces, thereby increasing the pollutant concentration on such surfaces.

### 2.16.5 Forms of Moisture on Surfaces

This section will discuss how moisture may form as a result of the atmospheric conditions previously discussed. Moisture may form on a surface because of the local RH, via the deposition of rain, fog, and wet aerosols, or because of wetting of hygroscopic salts on the surface.

#### 2.16.5.1 Effect of RH on Clean Surfaces

A surface exposed to ‘humid’ air will adsorb moisture and build up monolayers on the surface. Immediately upon exposure, OH layers will develop on the surface.<sup>14</sup> With further exposure, additional water layers are adsorbed, with the number of layers being dependent on the hydrophobic or hydrophilic nature of the surface, the density of defects on the surface, and the RH of the air. Estimates of the number of monolayers vary from 1 to 2 layers at 40% RH, 2–5 at 60% RH, to 6–10 at 100% RH.<sup>92</sup> It is generally accepted that below 60% RH the monolayers are too thin to sustain the electrochemical corrosion process.

#### 2.16.5.2 Effect of Aerosols/Raindrops

Aerosols show a significant variation in size range depending on the RH of the air and the history of the aerosol. Wet aerosols of marine origin<sup>91</sup> will have a size range of  $5\text{--}120 \mu\text{m}$  and after impact on the surface they will reform into roughly spherical-cap shaped droplets (with the contact angle defined by the surface energy). In general, aerosol droplets falling onto a surface will only cover a fraction of the surface and will, therefore, remain isolated with significant areas of ‘dry’ metal separating the droplets. In contrast, when rain impacts a surface, a high fraction of the surface will become covered by drops, which will undergo coalescence until they reach the critical size for drop movement, or they may be scavenged by a moving drop.

### 2.16.5.3 Rewetting of Surfaces and Condensation

On a clean surface, condensation will occur when the air close to the surface is at 100% RH. The temperature of the surface may vary from that of the ambient air and, therefore, the RH close to the surface may be different from that of the ambient air.

The evaporation of aerosols or rain on surfaces may leave crystallized salts, many of which may be hygroscopic. These salts will wet when the surface RH is greater than the DRH of the contaminant salts. The DRH of a number of common pollutants is given in [Table 4](#). A study by Cole *et al.*<sup>93</sup> compared the nature of surface contaminants with the wetting behavior of wetness sensors attached to metal plates and found that there was a high correlation between the DRH of the salts present and the wetting point of the sensor. Further, the nature of the salts present (and hence the wetting point of the sensor) was highly dependent on location, with severe marine sites contaminated with  $\text{MgCl}_2$  and  $\text{NaCl}$ , marine sites contaminated with  $\text{NaCl}$ , severe industrial sites contaminated with  $(\text{NH}_4)\text{HSO}_4$ , and moderate industrial sites with a marine influence contaminated with  $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$ ,  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NaHSO}_4$ , and  $\text{NH}_4\text{NO}_3$ .

The wetting of such crystalline salts will occur when

$$\text{RH}_s > \text{DRH of any contaminating salt} \quad [59]$$

where  $\text{RH}_s$  is the RH at the metal surface.

An alternative but equivalent expression can be expressed in terms of time of condensation (TCD), tendency to condensation (TCON), and vapor pressure, so that TCD is defined as

$$\text{TCD} = \text{time when TCON} > 0 \quad [60]$$

TCON is simply the difference between the vapor concentration of the air ( $V_a$ ) and the saturation vapor concentration at the metal surface ( $V_s$ ) required for condensation (vapor pressure is in Pascals):

$$\text{TCON} = V_a - V_s \quad [61]$$

and

$$V_s = (\text{RH}_c/100)$$

$$\exp(22.565 - 2377.1 T_s^{-1} - 33623 T_s^{-1.5}) \quad [62]$$

where  $T_s$  is the surface temperature (K) and  $\text{RH}_c$  accounts for the hygroscopicity of contaminating salts, which can be approximated by the DRH of any contaminating salt:

$$V_a = V_{as} \times \text{RH}/100 \quad [63]$$

where  $V_{as}$  is the saturation vapor pressure of the adjacent air, which is given by the following equation:

$$V_{as} = \exp(22.565 - 2377.1 T_a^{-1} - 33623 T_a^{-1.5}) \quad [64]$$

where  $T_a$  is the air temperature.

### 2.16.5.4 Evaporation

Evaporation of moisture from a surface covered with hygroscopic salts can be understood using either the surface RH concept or partial vapor pressure concept. Thus, wetted salts will begin to dry when the surface RH is less than the DRH of the contaminating salt or when the TCON is negative. However, to determine either of these parameters it is necessary to know the temperature of the metal surface.

#### 2.16.5.4.1 Surface temperature of plates

Metal surfaces exposed to the environment will undergo a diurnal cycle, heating up during the day (due to solar heating) and cooling down at night (because of the emission of radiation to the night sky), with both processes modulated by convective interaction with air. The extent of both heating and cooling will depend on a range of environmental factors, including cloud cover, wind speed, and the state of the surface.<sup>94,95</sup>

Condensation and evaporation will tend to reduce this diurnal cycle – condensation will release latent heat restricting further undercooling, while evaporation of moisture films after sunrise will cool surfaces, reducing solar heating. As a result, it may take significant time for metal surfaces to dry after sunrise. Predicted undercooling of a zinc plate openly exposed to the night sky is presented in [Figure 17](#) as a function of temperature. It is apparent that undercooling does not exceed 2.5 °C (still air, clear sky, 50% RH). The RH affects the extent of condensation and the latent heat released during condensation, so that on a clear night with 75% RH, a plate would undercool less than on a clear night with 50% RH. A breeze of 1 m s<sup>-1</sup> significantly reduces undercooling, as does cloud cover.

The rate at which zinc plates heat up after sunrise is presented (for dry plates) in [Figure 18](#) as a function of incident solar radiation which in turn is a function of the time of day. Thermal equilibrium is assumed. [Figure 18](#) can be matched with the solar radiation level for a given location. For example, measured data for Melbourne (latitude 38° S), Australia, indicates that on a clear day close to the September solar equinox (spring), the solar radiation

levels will be 171, 376, and  $696 \text{ W m}^{-2}$  at 1, 2, and 4 h respectively after sunrise, while on a cloudy day they will be 28, 68, and  $222 \text{ W m}^{-2}$  at 1, 2, and 4 h respectively after sunrise. From Figure 18, it is clear that, as a function of solar radiation, the increase in temperature on a cloudy and sunny day is the same. Of course, much less radiation reaches the surfaces on a cloudy day, so the temperature rise on a plate is much lower. Wind dramatically decreases the temperature rise because of forced thermal convection, with a wind speed of  $5 \text{ m s}^{-1}$  more than halving the rise. Figure 19 (from Cole *et al.*<sup>96</sup>) compares the temperature rise of a dry plate with that of a wet plate. The cooling effect of evaporation dramatically

**Figure 17** Predicted undercooling of a metal plate at different RHs. The breeze is  $1 \text{ m s}^{-1}$ . Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2006**, 41(1), 67–76.

**Figure 18** Predicted heating rate as a function of solar radiation for dry plates. Thermal equilibrium is assumed and the solar radiation is a function of time of day. Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2006**, 41(1), 67–76.

reduces surface heating. This reduction is closely tied to the ambient conditions (temperature and RH) that control evaporation.

#### 2.16.5.4.2 Evaporation rate

Figure 20 (from Cole *et al.*<sup>96</sup>) shows the evaporation rates on a metal surface (assuming a continuous film) for a variety of environmental conditions as a function of time after sunrise. The rate of evaporation is clearly influenced by surface temperature, as discussed above. With clear skies, a modest wind ( $5 \text{ m s}^{-1}$ ) and not excessive humidity (75%), a moisture film of  $200 \mu\text{m}$  will have evaporated an hour after sunrise. Evaporation actually starts before sunrise as the minimum temperatures (under these conditions) generally occur an hour before sunrise. In contrast, on a cloudy, still day of high humidity (95%), the same moisture film will still not have fully evaporated 4 h after sunrise.

A more precise understanding of the relevance of these effects to corrosion can be obtained if we calculate the time for evaporation of common aerosols. Using the data of Fitzgerald,<sup>35</sup> it can be estimated that a wetted aerosol on the metal surface will have a size range of  $2\text{--}120 \mu\text{m}$  with a median of  $12 \mu\text{m}$  and that a nonequilibrium aerosol (with a solids concentration equal to that of seawater) will have a size range of  $5\text{--}230 \mu\text{m}$  with a median of  $23 \mu\text{m}$ . The time for aerosols with median and extreme dimensions to evaporate is given in Table 12 (from Cole *et al.*<sup>96</sup>). It is apparent that, at least for some aerosols,

**Figure 19** Comparison of temperature rise on a dry plate with that of a wet plate. Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2006**, 41(1), 67–76.

**Figure 20** Evaporation rates on a metal surface assuming a continuous film of water. The assumed solar radiation 4 h after dawn is  $696 \text{ W m}^{-2}$  on a clear day and  $222 \text{ W m}^{-2}$  on a cloudy day. Reproduced from Cole, I. S.; Paterson, D. A. *Corros. Eng. Sci. Technol.* **2006**, 41(1), 67–76.

**Table 12** Time to dry (hours) for aerosols of given surface radii

Conditions	Surface radius ( $\mu\text{m}$ )			
	12	23	120	230
Cloud, no wind, 75% RH	Just after dawn	1	3	4
Clear, no wind, 75% RH	Just after dawn	0.6	1.5	2
Cloud, $5\text{ m s}^{-1}$ , 95% RH	Just after dawn	1.1	2.8	3.7
Cloud, $5\text{ m s}^{-1}$ , 75% RH	Prior to dawn	Prior to dawn	0.6	1.7

evaporation will take several hours. Many workers suggest that a peak in corrosion rate occurs during the evaporation phase, as salt concentrates and oxygen diffusion paths shorten.

Cole *et al.*<sup>65</sup> have documented experimentally the duration of periods of wetness that occur on wetness sensors attached to zinc plates that are openly exposed to the atmosphere in a range of locations around Australia.<sup>97</sup> They found that periods of wetness could be divided in three modes which they labeled Mode A, Mode B and Mode C. Mode A are short daytime wetness events with an average duration of  $\sim 2\text{ h}$  (they result from either hygroscopic wetting of deposited salts or rainfall but are of short duration as daytime evaporation is rapid). Mode B are nighttime wetness events that occur when condensation occurs in the evening and evaporation the next morning. The duration of the wetness period varies depending on the severity of the location (and thus the nature of deposited salts) from an average of 10 h in benign (inland) sites to 20 h in severe marine locations. Mode C is wetness periods that last more than 1 day; they are generally associated with the deposition of salts with low DRH (e.g.,  $\text{MgCl}$ ) so that surface RH may not dry out the wetted salts on some days. Again, the duration depends on the severity of the site raging from an average of 72–120 h in marine and severe marine sites.

#### 2.16.5.4.3 Evaporation and condensation on a porous surface

The above analysis refers to clean surfaces; however, on a corroded surface the situation may be more complex. First, many oxides are themselves hygroscopic, and second many oxides are porous and, therefore, when aerosols or raindrops are deposited onto such porous oxides, some of the solution will be absorbed into the pores and will subsequently evaporate, leaving contaminants within the pore structure. In these circumstances, capillary forces may alter the conditions for evaporation and condensation in the

**Table 13** Effect of pore size on tendency to condensate formation

Pore size ( $\text{\AA}$ )	RH for condensation (%)	%TCD (100)	%TCD (75)
Flat surface	100	4.6	43.5
360	98	7.5	45.3
94	90	19.8	52.1

% TCD (100) is the % time the tendency to condensation (TCO) is positive when the surface wetting occurs at 100% RH while % TCD (75) is the % time the TCO is positive when the surface wetting occurs at 75% RH.

pores, making it possible for condensation to occur in an atmosphere of less than 100% RH. These effects are best explored using the differential vapor pressure approach, where the relative lowering of the saturated vapor pressure in pores is given by Thomson's equation.<sup>98</sup>

$$p = p_o e^{-2\sigma M / \rho R T r} \quad [65]$$

where  $p$  and  $p_o$  are the saturated vapor pressures above a concave meniscus of radius  $r$  and a plane surface, respectively,  $\sigma$  is the surface tension of the liquid at absolute temperature  $T$ ,  $\rho$  is its density and  $M$  is its molecular weight of the condensing gas, and  $R$  is the gas constant. It can be estimated that capillary radii of 360, 94, and  $30\text{ \AA}$  will reduce the RH for condensation to 98, 90, and 70% respectively. It has been argued<sup>99</sup> that this effect may explain the observation that steel still corrodes at  $\sim 70\%$  RH, as ferric oxide gel has pore sizes  $\sim 30\text{ \AA}$ ,<sup>100</sup> and therefore, pore condensation may occur. Correspondingly, the period that moisture remains in pores may be considerably greater than that when it is free on the surface. The percent time that the tendency for condensation both on a clean surface and on a contaminated surface is greater than zero is given in Table 13, and compared to that for a clean pore and one contaminated with NaCl when both surfaces are exposed for a year in Canberra. It is apparent that even coarse pores significantly increase

the time when condensation is favored, both with and without chloride contamination, although the effect is more marked in the absence of chloride. Pore condensation and delayed evaporation may be relevant for metals with porous oxide, such as zinc, and could significantly change the wetness periods for these materials.

### 2.16.6 Summary of Environmental Conditions

The analysis in [Section 2.16.3.1](#) indicated that pollutant deposition onto a surface may occur by gaseous absorption into a moisture film, or by deposition of aerosol or of rain. As outlined in [Section 2.16.1.3](#), the composition of gases, aerosol, and rain drops will be affected as they are transported by atmospheric processes. However, the scale of these transport processes is likely to be quite different. Gases, particularly reactive gases, will not be transported far from their sources; aerosols may form relatively close to the pollutant source but may be transported significant distances, while the processes of rain drop formation are complex and will not bear a direct relation to pollutant sources. Thus, it is to be expected that the concentration of atmospheric gases will be highly influenced by local pollutant sources, and aerosol

concentration will also be influenced by local sources but concentrations will spread significantly from these sources, while rain water chemistry will be affected more by the pollutants in a region rather than in one locality.

In [Table 14](#) some key parameters defining gaseous concentrations, aerosols, and rain water chemistry are given for marine, industrial, urban, rural, and remote locations from data presented in this chapter. The table should only be taken as indicative and does not attempt to define the effect of particular local sources on pollutant levels.

### 2.16.7 Surface Reactions

#### 2.16.7.1 Equilibrium Considerations

The conditions within the rain droplet or aerosol may determine the stability of both common metal oxides and the underlying metal. Consider zinc, which in dry environments is covered with a zincite ( $\text{ZnO}$ ) film and which rapidly transforms to zinc hydroxide in the presence of moisture films. The potential–pH diagram of zinc– $\text{CO}_2$ – $\text{H}_2\text{O}$  system<sup>101</sup> (at 25 °C) with Graedel's<sup>101</sup> regimes for dew, rain, and fog and the stability lines for  $\text{H}_2\text{O}$ ,  $\text{H}_2\text{O}_2$ , and  $\text{O}_3$  is presented in [Figure 21](#) (modified with the original from Graedel<sup>101</sup>). At the typical rain regime or fog regime

**Table 14** Summary of gaseous concentration, aerosol type and rain water composition ( $\mu\text{eq l}^{-1}$ ) for marine, industrial, urban, rural, and remote locations

Location type	Marine	Industrial	Urban	Rural	Remote
Gaseous (mixing ratio)					
$\text{SO}_2$ (ppt)	260	1500	160–1500	160	20
$\text{H}_2\text{S}$ (ppt)	65	365	365	35–60	3.6–7.5
$\text{NO}_x$ (ppb)	0.2–1000	10–1000	10–1000	0.2–10	0.02–0.08
$\text{O}_3$ (ppb)	20–40	100–400	100–400	20–40	20–40
Aerosols					
pH	0–9.5	–1–2.4	1.9–3		
Major species	$\text{NaCl}$ , $\text{MgCl}$	$\text{H}_2\text{SO}_4$ , $(\text{NH}_4)_3\text{H}(\text{SO}_4)_2$ , $(\text{NH}_4)_2\text{SO}_4$ , $\text{NH}_4\text{HSO}_4$	$\text{NH}_4\text{NO}_3$ , $\text{NH}_4\text{Cl}$ , $(\text{NH}_4)_2\text{SO}_4$		Dust, pollen plant waxes
Secondary species	$\text{Na}_2\text{SO}_4$ , $\text{H}_2\text{SO}_4$ , $\text{NH}_4\text{HSO}_4$ , $(\text{NH}_4)_2\text{SO}_4$ and $\text{NH}_4\text{NO}_3$ . $\text{NaHSO}_4$		$\text{NaNO}_3$		
Rain water					
pH	4–5.6	4.2–7.3	4.4–6.1	3.6–5.8	5.6–6
$\text{Cl}^-$	100–1300	9–142	10–27	3–25	1–1300
$\text{NO}_3^-$	3–10	40–140	13–140	3–25	3–10

$\text{NH}_4^+$	2–10	30–200	10–30	2–20	2–10
$\text{Ca}^{2+}$		20–300	2–35	2–20	80

**Figure 21** Potential-pH diagram for the system Zn-CO<sub>2</sub>-H<sub>2</sub>O at 25 °C for a concentration of zinc ions of 0.1 M and a concentration of H<sub>2</sub>CO<sub>3</sub> of 1 \*10<sup>-5</sup> (this is the concentration in equilibrium with gaseous concentration of CO<sub>2</sub> of 340 ppmv). Modified from Graedel, T. E. *J. Electrochem. Soc.* **1989**, 136, 19C-2003C.

the surface Zn(OH)<sub>2</sub> film and the underlying Zn metal are not the stable phases, and rather Zn<sup>2+</sup> is the stable form. Therefore, dissolution of the zinc hydroxide is expected with the enrichment of the zinc ion concentration in solution. Stable oxide growth would not be expected. This enrichment of zinc ions in solution would then lead to precipitation of solid species.

A more complex situation occurs in the corrosion of iron. In [Figure 22](#), a potential-pH diagram<sup>69</sup> is given for the Fe-H<sub>2</sub>O system (at 25 °C) with the addition of the stability lines for H<sub>2</sub>O, H<sub>2</sub>O<sub>2</sub>, and O<sub>3</sub>. The diagram indicates that in many of the conditions commonly observed in dew rain and fog, the stable phase is either FeOOH or Fe<sup>2+</sup> at low pH values. These low pH values could occur either in fog or during the evaporation phase of dew or rain. However although the initial corrosion product may be Fe<sup>2+</sup>, the intermediate corrosion products are mixed Fe(II) and Fe(III) oxides and the final products contain only Fe(III).<sup>102</sup> The development of these oxides can in part be attributed to the reactive oxidants, hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), the OH<sub>2</sub> and the hydroperoxyl radical (HO<sub>2</sub>). It will be recalled that the work of Graedel and Goldberg<sup>103</sup> demonstrated

that small but significant concentrations of these oxidants could develop in rain droplets. The free radical and the peroxide reaction are likely to be<sup>103</sup>

and

If solutions contain oxidants, the redox potential of the solutions will be influenced by the reduction/oxidation of these oxidants which may influence the stability of oxides and the passivation of metal surfaces. For example, according to Pourbaix<sup>102</sup> in a dilute solution of hydrogen peroxide the iron may be in the domain of the corrosion of iron (formation of Fe<sup>2+</sup>) and the reduction of hydrogen peroxide (point A on [Figure 22](#) at  $E = -0.200$  V and pH = 5.7), so that the following reactions could occur:

The overall reaction will be

In contrast with a concentrated solution of hydrogen peroxide, iron would be in a passive domain with stable oxides (point B on [Figure 22](#)) and hydrogen peroxide is in its domain of double instability. In this region (below line c and above line d in [Figure 22](#)), hydrogen peroxide may decompose into both water and oxygen according to the following equations:

The overall reaction will be

Thus, the metal surface may facilitate the decomposition of hydrogen peroxide and the evolution of gaseous oxygen, but the iron will remain in the passive state.

However, hydrogen peroxide can act to oxidize sulfite to sulfates as outlined in [eqn \[19\]](#). This will decrease the pH and the H<sub>2</sub>O<sub>2</sub> concentration so that the critical parameter in determining if the peroxide concentration is such that Fe is in a passive or active region of the potential-pH space is the relative concentrations of sulfite and peroxide. Thus, if [H<sub>2</sub>O<sub>2</sub>] > [HSO<sub>3</sub><sup>-</sup>], H<sub>2</sub>O<sub>2</sub> will not be completely

**Figure 22** Potential-pH diagram for the system Fe-H<sub>2</sub>O at 25 °C. Derived from Pourbaix, M. *Atlas of Electrochemical Equilibria in Aqueous Solutions*, 2nd English Edition; National Association of Corrosion Engineers: 1440 South Creek Drive, Houston Texas 7704, 1974; the approximate regimes for fog, rain, and dew are derived from Graedel, T. E.; Frankenthal, R. P. *J. Electrochem. Soc.* **1990**, *137*, 2385-2394.

depleted and hence may be available to passivate the metal surface.<sup>69</sup>

In contrast with the marked changes with the stability of the Fe phases because of the action of the oxidants, they have little effect on the equilibrium condition for the zinc system. On [Figure 21](#), the potentials for reduction of ozone or hydrogen peroxide (at pH values likely to occur in rain water or aerosols) fall in the stability range for Zn<sup>2+</sup>. Hence, the presence of these oxidants will further promote the corrosion of zinc.

Although the *E*-pH diagrams are useful, they only define the equilibrium conditions for relatively simple systems. In reality the kinetics of the corrosion processes are critical in determining the corrosion rate and the corrosion product while both rain drops and aerosols are multicomponent systems involving a wide range of aqueous species (chlorides, sulfates, carbonates, oxidants) and continuous gaseous absorption from the environment. Part of the dynamic nature of this system comes from the electrochemical processes themselves which can induce

separation of anodic and cathodic areas, differential pH at these zones and ion migration driven by local potentials.

#### 2.16.7.2 Influence of Electrochemical Processes on Moisture Film Stability and Chemistry

The establishment of separated anodic and cathodic areas may have significant impact on the distribution of species within a droplet. Two examples will illustrate this effect: the first, secondary spreading on zinc is a relatively long range effect, while the second, the development of anodic and cathodic zones associated with particular intermetallic zones containing aluminum 2000 and 7000 series is more local. Neufeld *et al.*<sup>104</sup> studied the effect of wetting fine NaCl crystals on zinc surfaces. It was found that in high humidities (>75% RH) deposited salt crystals rapidly wet forming roughly hemispherical moisture droplets. After a relatively short period, a fine moisture film spreads out from a central droplet. Scanning Kelvin

probe studies indicated an electrochemical cell developed, with the central drop becoming anodic and the secondary spread region cathodic. High pH developed in the secondary spread region and slightly acidic pH values in the central droplet. Neufeld *et al.*<sup>104</sup> demonstrated that significant ion migration occurred with cations (particularly  $\text{Na}^+$ ) migrating into the secondary spread region and anions into the central anodic zone. Correspondingly, after the drop had dried out at the completion of the experiment, quite different corrosion products were found in the two zones with the main product in the secondary spread zone being zinc hydroxycarbonate and the main products in the inner anodic region being zinc hydroxychloride (simonkolleite) and sodium zinc hydroxysulfate chloride (gordite).<sup>91</sup>

Secondary spreading is significant for a number of reasons. Primarily, the establishment of a very large cathodic zone removes any possibility of cathodic limitations for the corrosion process and thus may increase the initial corrosion processes. However, the high pH in the secondary spread area provides ideal conditions for the absorption of carbon dioxide (via eqns [15]–[17]). At pH 9 the carbonate ion concentration in solution is  $10^6$  times that at a pH of 6. High carbonate concentrations will lead to the precipitation of zinc hydroxy carbonate. Of course, the absorption of carbon dioxide will also tend to neutralize the alkaline pH. The development of significant coverage of the zinc surface by zinc-hydroxy carbonate will limit corrosion in subsequent wetting cycles. Muster *et al.*<sup>105</sup> have demonstrated that the carbonate blocked chloride penetration to anodic sites on the metal surface to a much greater extent than zinc hydroxycarbonate.

Such secondary spreading has also been observed in steel<sup>106</sup> and copper.<sup>107</sup> However, the phenomenon was not observed on aluminum when exposed to the identical condition.<sup>108</sup> The work on copper also shows interesting synergies between secondary spreading and the absorption of gaseous species in an analogous manner to that observed for zinc. Chen *et al.*<sup>108</sup> wetted a NaCl crystal on a copper plate in an atmosphere containing 150 ppb  $\text{SO}_2$  and two different levels of  $\text{CO}_2$  (<5 ppb and ambient 350 ppb). They observed that a narrow band of secondary spreading occurred with an alkaline pH occurring in the spread area, with sulfate and dithionate ( $\text{S}_2\text{O}_6^{2-}$ ) species observed in the secondary spread zone, and the corrosion products nanotokite ( $\text{CuCl}$ ) and pantacamite ( $\text{Cu}_2(\text{OH})_3\text{Cl}$ ) observed in the central droplet region. It is known that  $\text{Cu}^{2+}$  may catalyze the oxidation of S(IV) to S(VI) in an analogous manner to that of the other

transition metal ions  $\text{Mn}^{2+}$  or  $\text{Fe}^{2+}$  (refer to eqn [16]). Thus, the absorption of  $\text{SO}_2$  and its dissociation via eqns [11] and [12] are promoted by the high pH in the secondary spread zone.  $\text{Cu}^{2+}$  catalyzed oxidation of the sulfite may occur by one of the following reactions<sup>76</sup>:

or

The absorption of  $\text{SO}_2$  and the formation of sulfate will lower the pH in the secondary spread area and secondary spreading will cease. The separation of the droplet into cathodic zones and anodic zones in the central area will lead to a higher level of  $[\text{H}^+]$  in the anodic zone which will encourage copper dissolution and the precipitation of nanotokite and pantacamite (rather than NaCl).<sup>108</sup>

Thus, secondary spreading can lead to significant variation in pH and species concentration (both by variations in gaseous absorption and by migration), and so it can lead to the formation of different oxides with the consequence of further corrosion.

Dynamic interactions also occur involving solution chemistry, local pH, corrosion product formation, and electrochemistry at a finer scale. The trenching observed around cathodic intermetallics in aluminum AA2xxx and AA7xxx series alloys can illustrate these effects (this chapter will not attempt to cover the interesting and involved interactions of intermetallics and electrochemistry of these alloys will be discussed elsewhere<sup>109</sup>). To achieve the required strength, the formation of intermetallics is required in these structural aluminum grades. Some of these intermetallics – notably the Al–Cu–Fe–Mn group,<sup>110,111</sup> including  $\text{Al}_6(\text{CuFeMn})$ ,  $\text{Al}_2\text{Cu}$ ,  $\text{Al}_7\text{Cu}_2\text{Fe}$ , and  $\text{Al}_{20}\text{Cu}_2(\text{FeMn})_3$  – have a very strong ability to sustain a cathodic current. Birbilis and Bucheit<sup>110</sup> found that at the corrosion potential of AA7075–T651 in NaCl (i.e.,  $-965 \text{ mV}_{\text{SCE}}$ )  $\text{Al}_7\text{Cu}_2\text{Fe}$  and  $\text{Al}_2\text{Cu}$  could support cathodic currents in excess of 310 and  $470 \mu\text{A cm}^{-2}$ , respectively while Schneider *et al.*<sup>111</sup> showed the cathodic current on  $\text{Al}_{20}\text{Cu}_2(\text{FeMn})_3$  to be ten times greater than that measured on AA2024–T3 alloy surfaces. The high cathodic current sustained by these intermetallics can lead to localized pitting corrosion and to trenching around Al–Cu–Fe–Mn phases.<sup>112–116</sup> The exact mechanism of trenching is still subject to debate with some researchers<sup>112</sup> suggesting that it may be interpreted as galvanic corrosion between the particle and the matrix, and others<sup>113,114</sup> indicating that it is a form of

etching under the high pH conditions occurring at the cathodic intermetallics. In fact Park *et al.*<sup>113</sup> have found pH values  $\sim 9.5$  at around these particles. Under these high pH conditions, it is suggested<sup>114</sup> that the aluminum matrix undergoes cathodic corrosion, together with dissolution of the oxide film producing aluminate ions and hydrogen gas according to the equation

The rate of eqn [77] is highly pH dependent. In fact, Park *et al.*<sup>113</sup> and Vukmirovic *et al.*<sup>115</sup> have found that increased buffering of the solution decreases the rate of pitting around the intermetallic particles which they attribute to the inability to sustain high localized pH values in a buffered solution. As highlighted previously in atmospheric conditions, highly buffered solutions can arise from various acid/salt couples such as the bisulfite/sulfite reactions (eqn [12]). The formation of colloidal alumina gels have been observed<sup>113,116</sup> between anodic and cathodic regions on the surface and these may help maintain both potential and pH differences between these regions. In fact Ilevbare *et al.*<sup>116</sup> have reported that as high pH develops at cathodic sites and low pH at anodic sites, increased galvanic potential differences are created.<sup>116</sup> Thus, under atmospheric conditions, an interplay between local electrochemical activity and local pH may arise, with corrosion product or gel formation controlled by the general chemistry of the droplet solution.

#### 2.16.7.2.1 Oxide precipitation and stability

The fact that a surface is corroding implies that there is metal ion formation, as well as diffusion or migration through the oxide layer, and in many cases, these processes are highly influenced by oxide stability, dissolution, and growth. Oxide stability in its turn is affected by the local pH and ion concentration, which as discussed above, are influenced not only by the original pH of the deposited moisture and subsequent aqueous reaction but also by the establishment of local anodes and cathodes. These interactions will be discussed in relation to the aluminum and zinc systems.

The typical form of an oxide film on aluminum exposed to water or water vapor consists of a thin layer of  $\gamma\text{-Al}_2\text{O}_3$  covered with a thin layer of boehmite ( $\gamma\text{-AlOOH}$ ) which in turn is covered with bayerite ( $\text{Al}(\text{OH})_3$  which can be written as  $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ ).<sup>117</sup> The stability data of boehmite and bayerite, along with that of CuO and hydrated copper

oxide ( $\text{Cu}(\text{OH})_2$ ) are presented in Figure 22 from the data of Pourbaix.<sup>102</sup> It is evident that very low pH values are required for aluminum oxides to show significant solubility (less than 2.4 for boehmite). In fact only in acidic fogs and very acidic aerosols (for example, referring to Figure 1, the aerosols in the  $\text{NH}_3\text{-SO}_4$  system, where the ammonia/sulfur dioxide ratio is less than 0.5 so that  $\text{H}_2\text{SO}_4$  is the dominant and  $\text{NH}_4\text{HSO}_4$  the secondary species) will boehmite dissolve directly. However, these low pH values may occur in the evaporation phase of rain drops or condensate (i.e., dew) or if localized pH changes occur in association with pitting corrosion or oxygen differentials. However, at a pH of 4 some dissolution of the oxide may occur, particularly in association with defects or cracks in the oxide film. Thus when acid fogs, acidified rain, or acid aerosols (either industrial or marine – but affected by absorption of acids) fall on an aluminum surface some dissolution of the oxide layer is expected, with the electrolyte solution and the underlying metal substrate being in contact through cracks and pores in the surface. Aluminum ions may diffuse through the pores and in sulfate rich environments may form amorphous aluminum sulfate hydrate –  $\text{Al}_x(\text{SO}_4)_y(\text{H}_2\text{O})_z$ , which will gradually transform into aluminate,  $\text{Al}_2(\text{SO}_4)(\text{OH})_4 \cdot 7(\text{H}_2\text{O})_2$ . The pitting may commence beneath defects in the oxide and the progression of the pitting (and further dissolution of the oxide) may be supported by the autocatalytic nature of the pitting process, when anodic regions occur at the bottom of the pit and because of the strong oxygen differential between the bottom and the top or exterior of the pit, cathodic zones also occur in these regions. The formation of gel structures by aluminum sulfate hydrate or other amorphous materials will tend to occur at the mouth of the pit (where the pH is higher) stabilizing the pH and oxygen differentials. In the chloride rich solutions generated by marine aerosols, chloride ions may complex with  $\text{Al}^{3+}$  ions at anodic sites and, thereby, prevent the formation of aluminum hydroxides. Further, aluminum hydroxide chlorides may form either by chlorination of the surface  $\text{Al}(\text{OH})_3$  or in solution. Further reactions with chloride ions can lead to the formation of Cadwaladerite  $\text{AlCl}(\text{OH})_2 \cdot 4\text{H}_2\text{O}$  and then aluminum chloride  $\text{AlCl}_3$ .

Clearly, this reaction is favored in acidic and chloride

rich environments. The dissolution of the boehmite layer will then permit further access of the solution to the substrate and thus enhanced corrosion.

The situation above is very similar for structural alloys with a large range of intermetallics. First, the oxide layers above the intermetallics tend to be thinner with more defects, so that the electrolyte can more easily move through to the substrate. Second, as discussed in a previous section, certain intermetallics may establish large cathodic currents which can reinforce a strong pH difference between the cathodic intermetallic and the anodic matrix, increasing the corrosion rate and promoting more aggressive pitting in the matrix. These potential and pH differences can be supported by the formation of gels as highlighted above.

A second aspect is illustrated by the role of Cu in the corrosion of aluminum alloys. Copper is a more noble metal than aluminum and, therefore, during the corrosion processes will accumulate at the metal oxide boundary; it then migrates through the oxide to the surface where it may form clusters and act as cathodic sites. Copper that has entered into solution or any original copper in solution may be subsequently reduced back to copper metal on cathodic copper containing intermetallics. In the presence of  $\text{Cl}^-$  ions the formation of  $\text{CuCl}^+$  will lower the energy barrier for the deposition of copper onto aluminum that leads to secondary pitting. Thus, copper plating and secondary pitting may be promoted in solutions with moderate pH and high chloride content such as acidified marine aerosols, **Figure 23**.

In the zinc systems, it is meaningful to discuss corrosion that occurs as a result of secondary spreading and that occurs when conditions are not suitable for secondary spreading. If secondary spreading occurs, there is a wide separation of anodic and cathodic zones. In the cathodic regions, alkaline pH values develop and zinc hydroxycarbonate is observed to form both in the laboratory conditions and in the field. **Figure 24** from Graedel<sup>118</sup> gives the zinc carbonate stability diagram with the regime for marine aerosol added. It is evident that under typical conditions of rain, dew, or marine aerosol, zinc carbonate would not be expected to form. Therefore, the high pH and carbonate levels (up to  $10^3$ – $10^4$   $\mu\text{M}$ ) in secondary spreading zones favor the formation of the carbonate whereas it would not form in a 'stable' drop.

In the central anodic zone of the droplet, slightly acidic pH values develop and common corrosion products are gordiate, zinc hydroxy chloride, and

**Figure 23** Stability of boehmite, bayerite and  $\text{CuO}$  and  $\text{Cu(OH)}_2$ . Reproduced from Pourbaix, M. *Atlas of Electrochemical Equilibria in Aqueous Solutions*, 2nd English Edition; National Association of Corrosion Engineers: 1440 South Creek Drive, Houston, Texas 7704, 1974.

zinc hydroxy sulfate. Stability diagrams from Graedel indicated that both the hydroxy sulfate and hydroxy chloride have relatively limited stability regions that require sulfate and chloride concentrations in excess of  $10^2$  and  $10^3$   $\mu\text{eq l}^{-1}$  respectively and zinc ion levels greater than 0.1 M; both these are centered around a pH of 6.2. However, as the anion concentration increases, the pH stability range also increases so that at concentrations of  $10^5$   $\mu\text{eq l}^{-1}$  the hydroxy anions are stable from a pH of just below 6 to nearly 8. On metal surfaces exposed to a marine environment, the concentration of chloride and sulfate in deposited aerosols will range from 0.55 to 5.4 M, that is, from the concentration in seawater (in a freshly formed aerosol that has not yet equilibrated to the atmospheric conditions) to that at saturation point, when the RH is just above the deliquescent RH of the constituents of seawater. Thus, in the solutions formed by the deposition of wetted aerosols, although there will be sufficient chloride to promote the formation of zinc hydroxide chloride, there will not initially be sufficient zinc ions in solution. This may allow the formation of mixed cation OH anions and in fact Cole *et al.*<sup>91</sup> have observed the formation of gordiate after short periods of exposure. Thus, within the central zone of an aerosol droplet, subject to secondary spreading, gordiate and zinc hydroxy-chloride will form. As the droplet evaporates, the concentration of both anions and actions will increase allowing the formation of a wider range of salts such as zinc hydroxysulfate. In droplets that do not undergo secondary spreading similar processes will

occur in the central droplet; however, Cole *et al.*<sup>91</sup> found no evidence of the formation of zinc hydroxycarbonates. Traditional theories to explain how zinc hydroxycarbonate may form in marine chloride rich environments have suggested that zinc hydroxychloride may transform to the hydroxycarbonate with time; however, because of the high pH and carbonate concentration that occur in secondary spreading, the zinc hydroxycarbonate phase may form directly.

However, the zinc OH anions and particularly the hydroxychlorides are not stable under the common pH and chloride concentrations that occur in dew, rain, or fog (see Figure 24). Thus, it is quite possible that zinc hydroxychloride may dissolve under these types of moisture. In Figure 25, the concentrations of chloride and zinc ions that occur when zinc hydroxychloride powder (mass of 1.78 g) is placed in 1 l of a dilute solution of nitric acid with a pH of 4.5 and 6.5 are presented. It is evident that over a period of 500–1500 min (or ~8–24 h) significant chloride levels will build up in solution. Work by Cole *et al.*<sup>119</sup> indicated that moisture layers or droplets might exist on corroded surfaces for equivalent periods (dew may form early in the evening and last until after sunrise; likewise rain that falls in the late evening may not evaporate until the following sunrise) and, therefore, significant chloride concentration could build up

from the dissolution of these oxide layers, enhancing corrosion.

Both these examples indicate that there is a very strong interaction between the atmospheric conditions, forms of deposition, and electrochemical and surface reactions controlling corrosion. This is of course controlled by the pH and chemical composition of the deposited moisture layers, but it is also influenced by drop size and residency time of the drop.

#### 2.16.7.2.2 Specific features of the atmospheric corrosion of steel

While the interactions between the environment and steel are similar to those discussed for aluminum and zinc, the atmospheric corrosion of steel has a number of specific features associated with the following:

- The additional reduction and oxidation pathways provided by the existence and ready transformation between Fe(II) and Fe(III) oxides.
- The high porous and often quite thick physical nature of 'rust' on ferrous surfaces.
- The interactions of Fe with sulfur dioxide and its oxidation products, where  $\text{Fe}^{2+}$  may catalyze the reduction of sulfite to sulfate, while the sulfate ion may characterize the dissolution of iron.

The standard reactions that occur during the atmospheric corrosion of steel are the anodic partial reaction<sup>97</sup> of iron (eqn [69]) and a number of possible cathodic reactions,<sup>120</sup> including oxygen reduction (eqn [39]) and hydrogen reduction (eqn [35]). Hydrogen reduction should dominate over oxygen reduction at pH values less than 4; however, because of the dissolution of iron oxides the electrolyte on top of iron-based metals is well buffered<sup>121</sup> so that  $\text{H}^+$  reduction is negligible. However, a third cathodic reaction is the reduction of  $\text{Fe}^{3+}$  ions within the oxide scale, as first proposed by Evans<sup>122</sup>:

Stratmann<sup>123</sup> suggested that this reaction is critical in controlling and accelerating (relative to the corrosion rate without the redox reaction) the corrosion rate of ferrous alloys during wet and dry cycles. During the wetting of an existing oxide layer, Stratmann observed a corrosion rate much greater than that would be expected by oxygen reduction alone and therefore, proposed that the increased corrosion rate was due to the reduction of  $\text{Fe}^{3+}$  ions. He indeed demonstrated the phenomenon using *in situ* spectroscopy (showing that  $\gamma\text{-FeOOH}$  had in part transformed to

**Figure 24** Stability diagram for zinc carbonate (ZC) in aerated aqueous solutions with varying  $\text{H}_2\text{CO}_3$  content and pH at 25 °C and with zinc ion concentration of 0.1M. Reproduced from Graedel, T. E. *J. Electrochem. Soc.* **1989**, 136, C193–C203.

**Figure 25** Concentration in solution of  $\text{Zn}^{2+}$  and  $\text{Cl}^-$  ions due to the dissolution of a zinc hydroxychloride table (1.78 g) in a aqueous solution (1 l) with nitric acid added to give a pH of 4.5 and 6.5.

an  $\text{Fe}(\text{OH})_2$  phase).<sup>123</sup> Further, the oxide scale has a very large area and the formation of  $\text{Fe}^{2+}$  states within the  $\text{FeOOH}$  lattice will control the potential and can dramatically increase the rate of electron transfer reactions, notably oxide reduction, both during the later stages of wetting and during the drying cycle (the reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  being constrained to the initial wetting period). During the drying cycle, the corrosion rate shows a marked peak while the corrosion potential shifts to more anodic values. The increased corrosion current is associated with the increased availability of oxygen as the pathway from the atmosphere to the oxide layer shortens dramatically as the moisture layer thins down, while Stratmann proposed that the anodic shift is due to the precipitation of corrosion products in the concentrated thin moisture films, which block anodic metal dissolution and eventually dramatically slow the corrosion rate. Further, the  $\text{Fe}^{2+}$  states within the oxide are oxidized during the drying cycle, which reduces the rate of oxygen reduction (reversing the previous effect), and it is only when the oxide is rewetted and new  $\text{Fe}^{2+}$  states are created that electron transfer is again enhanced.

Therefore, in atmospheric corrosion it would be expected that the nature of the climatic cycle and the

nature of oxide layers would have a very pronounced effect on the corrosion rate. At a gross level, atmospheric sequences with a high number of wet/dry cycles are likely to promote a higher corrosion rate than more constant conditions. However, the duration of wet/dry cycles is also important, as Stratmann's work indicates that the extent of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  reduction in the wetting stage will control the extent of corrosion during the drying stage. Precise details of the kinetics of this transformation are not available in the literature; however, it is possible that during short wet/dry cycles, such as those attributed to wetting or aerosol/rain deposition and subsequent drying during the day (referred to as Mode A wetting in [Section 2.16.5.4](#)), a lesser quantity of  $\text{Fe}^{3+}$  is reduced and thus the corrosion rate is decreased relative to longer wet/dry cycles (overnight and multi-day wetting events, as detailed in [Section 2.16.5.4](#)).

The volume and porosity of the oxide layers will also be critical in controlling the corrosion rate. In this regard, there are two prime effects. First, as outlined in [Section 2.16.5.4.3](#), fine pores will increase the duration of wetness by reducing the RH level at which condensation will occur and also lowering the RH level at which evaporation will occur. Further, increasing the porosity of the oxide will also increase

the cathodic surface area that develops during a wet/dry cycle, thus increasing the corrosion rate. Therefore, it is probable that processes that increase the porosity of the rust layer (such as localized dissolution under acid aerosols) will also increase the overall corrosion rate. However, again there are no systematic studies of this currently reported in the literature.

The last significantly different effect (relative to aluminum and zinc) is the impact of gaseous SO<sub>2</sub> and sulfate compounds on the corrosion of ferrous metals. As outlined in Section 2.16.1.3.4, Fe(III) states may catalyze the oxidation of S(IV) compounds (e.g., HSO<sub>3</sub><sup>-</sup> or SO<sub>3</sub><sup>2-</sup>) to SO<sub>4</sub><sup>2-</sup> or other forms of S(VI). This in turn will promote greater absorption of SO<sub>2</sub> and further acidification of moisture layers. Within moisture layers containing sulfate compounds, sulfur is not consumed in the corrosion reactions, but may act as a catalyst according to the following reactions<sup>124,125</sup>:

Typically, one SO<sub>4</sub><sup>2-</sup> ion can catalyze the dissolution of more than 100 atoms of iron before it is removed by leaching, spalling of rust, or the formation of basic sulfate.<sup>125</sup> The combined effect of the enhanced absorption of SO<sub>2</sub> and the catalytic role of SO<sub>4</sub><sup>2-</sup> ion may be responsible for the very high dependence and rate of ferrous corrosion in industrial environments.<sup>126,127</sup>

There is extensive literature on the nature of ferrous rust products and it is beyond the scope of this review to detail this. A key point, however, is that as the redox reaction from Fe(III) to Fe(II) has a pronounced effect on cyclic corrosion, the development of Fe(III) compounds of greater stability should result in a decrease in the corrosion rate, while compounds of lower stability should result in higher corrosion rates. Partially for this reason, there has been great interest in the development of green rusts (GRs), which were initially identified by Stampfl.<sup>128</sup> A typical carbonate-based GR<sup>129</sup> is Fe<sub>4</sub><sup>2+</sup>Fe<sub>2</sub><sup>3+</sup>(OH)<sub>12</sub>CO<sub>3</sub>·2H<sub>2</sub>O. Reffass *et al.*<sup>130</sup> mapped the sequence of corrosion products that formed when carbon steel corroded in NaHCO<sub>3</sub>/NaCl electrolytes and found that pitting corrosion induced by anodic polarization of the surface in NaHCO<sub>3</sub> led to the initial precipitation of FeCO<sub>3</sub>, and that this FeCO<sub>3</sub> was then transformed to a species identified as a carbonate-based GR, which

later transformed to α-FeOOH. Further, in a study of the oxidation of Fe(II) compounds formed by mixing FeCl<sub>2</sub>·4H<sub>2</sub>O, NaOH and NaHCO<sub>3</sub> in solution, Reffass *et al.*<sup>130</sup> found that three redox couples developed: FeCO<sub>3</sub>/GR(CO<sub>3</sub><sup>2-</sup>), GR(CO<sub>3</sub><sup>2-</sup>)/α-FeOOH, and FeCO<sub>3</sub>/α-FeOOH. If such reaction sequences are reproduced in atmospheric corrosion, then the above redox reactions may have a major role in driving the corrosion rate in an analogous way to that discussed for the Fe(II)/Fe(III) redox couples.

## 2.16.8 Conclusion

An understanding of atmospheric corrosion requires a wide understanding of the transfer of pollutants and moisture to metal surfaces and the form and residence time of the pollutants and moisture on the surface.

Despite the enormous range of the species in the atmosphere, surprisingly few species play an active role in atmospheric corrosion. For a chemical species to promote corrosion, it must be transported and deposited onto the metal surface and it must also be reactive to the surface. These conditions are somewhat contradictory as species that are reactive will readily react in the atmosphere and, therefore, will not be available for surface reactions. Gaseous deposition into surface moisture layers, aerosol deposition, and rain deposition are the prime processes for pollutant deposition onto surfaces. Deposition of reactive gases will only be important close to the gas source, while aerosols will be of higher concentration close to the source but may also be transported significant distances from the source. The formation of rain and absorption of gases or aerosols into rain drops require a complex process including the formation of an aerosol, transformation of the aerosol into CCN, growth of the CCN to form a cloud droplet, and the falling of the rain drop and scavenging of gaseous and aerosol species during the fall. Thus, rain drop chemistry will reflect the regional level of pollutants rather than just the local level. Species such as ammonia, sulfates, chlorides, and (to a lesser extent) nitrates, that are readily absorbed into forms of atmospheric moisture such as aerosols or rain drops will be readily transported and deposited on surfaces. Oxidants such as ozone or hydrogen peroxide are of critical importance as they will both facilitate the oxidation of reduced species (such as sulfites), and thus promote further absorption, as well as controlling the redox potential of the deposited solutions. The pH of aqueous phases in the atmosphere will depend critically on the

balance between acidic (primarily oxides of sulfur and nitrogen) and alkali precursors (predominately the alkali metals and ammonia) and, therefore, can be very variable. Although relatively acidic aerosols may develop, rainwater solutions tend to be highly buffered and, hence, extremes in pH are rare.

Once deposited, pollutants, aerosols, and rainwater may have a number of effects which are mitigated by local micro climatic effects. The microclimate of exposed metal components is in general subject to strong diurnal cycles which are amplified by radiative effects (heating during the day and cooling at night by the emission of radiation of the surface to the night sky) so that low surface RH may occur during daylight hours and high RH at night. Many of the salts deposited in aerosols or rainwater are hygroscopic and so deliquescence of such salts can lead to a cyclic pattern of localized wetting and drying. Although rain can promote the deposition of pollutants and transfer of acidity to the surface, it may also remove pollutants from the surface. The effectiveness of pollutant removal is controlled by the rain intensity and the nature of the surface. Electrochemical and surface reactions may influence the form and chemistry of droplets on a surface. Perhaps the most dramatic example of surface processes inducing droplet instability is secondary spreading. In secondary spreading, a fine moisture film spreads out from the centralized drop, with the central drop forming the anode and the secondary spread region the cathode of an extended electrochemical cell. Alkaline pH develops in the secondary spread region which may promote particular gaseous absorption reactions. For example, in secondary spreading on zinc, the absorption of carbon dioxide and the enrichment of the secondary spread region in carbonate occur and the subsequent precipitation of zinc hydroxycarbonate is promoted. However, pH variations and local electrochemical cells may occur on a much finer scale. In aluminum alloys, copper-containing intermetallics may be preferred sites for cathodic reactions, with high pH in the vicinity of the intermetallics promoting the dissolution of the aluminum matrix. However, the ability of the solutions to sustain such local variations in pH is heavily influenced by their buffering capacity (highly buffered solutions will not support these local variations) which in turn is determined by the history of aqueous and gaseous reactions prior to deposition.

The solution chemistry will be controlled by the precipitation of new oxides and the stability of existing oxides. There can be sharp 'cycles' in ion concentration and pH of deposited moisture. For example in the zinc

system, the zinc hydroxy anions are stable at near neutral pH values and appreciable anion concentrations. These conditions can readily occur during the evaporation of aerosol or rain droplets and, therefore, precipitation of such zinc OH anions is readily observed under these conditions. However, when an aerosol or rain drop is first deposited, it will commonly be acidic with relatively low anion concentrations. Under these conditions, some of the existing surface precipitates are not stable and may dissolve.

Thus, atmospheric corrosion is influenced by a wide range of linked processes, both within the atmosphere and on the surface. However, as in general these processes relate to a relatively narrow band of chemical species, an adequate knowledge of the dynamics of atmospheric corrosion can be constructed.

This chapter focuses on corrosion and behavior of important engineering materials in seawater. As entire textbooks have been devoted to seawater and marine corrosion, it is clearly not possible to cover this subject in great detail in this chapter.

It is customary to define marine environments in terms of ‘zones’ in which materials might be exposed, *viz.*, atmospheric, splash and spray, tidal, immersion or submerged, and bottom-mud or sediment. This chapter addresses corrosion issues primarily pertaining to the immersion, tidal, and splash zones. Corrosion in marine atmospheres and bottom-mud is covered elsewhere in this book.

Materials are subjected to seawater conditions in numerous applications, for example, ships, pleasure boats, submarines, offshore platforms, subsea pipelines and telecommunications cables, wharfs, seawater-cooled power and chemical plants, desalination plants, fishing gear, and so on. Seawater is a critical resource for food (primarily fish), table salt, and conversion to freshwater (desalination). It is also the primary source for extraction of magnesium and subsequent production of its alloys.

As in so many other environments there is a multitude of factors, which can affect corrosion of materials in seawater. Many of these factors are interrelated, resulting in complicated behavior of materials in specific applications. The important influencing factors are reviewed first, followed by an analysis of the corrosion mechanisms and the behavior of common engineering materials in seawater. Finally, test methods in seawater environments are discussed briefly.

**2.18.2 Environment Characteristics**

Seawater covers ~70% of the earth’s surface. It is a highly complex medium that contains almost every element in the periodic table and a multifarious plethora of living organisms. Hence, it is sometimes described as a ‘living’ medium and considered to be the most corrosive of the natural environments.

**2.18.2.1 Seawater Constituents**

Conventional wisdom is that the corrosivity of seawater is because of its salt (primarily NaCl) content. However, as discussed later in this section, it is not the salt *per se*, but other constituents – especially the dissolved oxygen (DO) and pollutants such as sulfides that often play critical roles. The total salt content is typically expressed in terms of salinity and/or chlorinity. Salinity is the total solid matter (grams) in one kilogram of seawater (after all the organic matter has been oxidized, carbonate converted to oxide, and bromine and iodine replaced by chlorine). From an analytical viewpoint, it is easier to determine the chlorine content, which is expressed as chlorinity – the total amount of chlorine (grams), plus equivalent chlorine assumed to replace bromine and iodine, in 1 kg of seawater. Salinity is related to chlorinity by the following empirical expression:

$$\text{Salinity} = (1.80655 \times \text{Chlorinity}) + 0.03$$

Salinity and chlorinity are usually expressed as grams per kilogram or parts per thousand (g kg<sup>-1</sup>, ppt or ‰). Multiplying by 1000 converts g kg<sup>-1</sup> or ppt to parts per million (ppm). Salinity can also be considered as total dissolved solids (TDS), stated as mg l<sup>-1</sup> (ppm). The properties of seawater can vary considerably by geographical location, seasons, and water depth. **Table 1** shows a comparison of the relative approximate salinities of a number of seas and oceans in the world. River outflows, evaporation, rainfall, melting ice, wind, and wave action – all can exert a strong influence on salinity. Littoral waters are often rendered brackish (*i.e.*, less salty) due to significant river outflow and may contain considerable sediments and pollutants.

The ‘average’ salinity of open ocean waters (*i.e.*, well away from land) is in the range ~32–36 ppt, and the corresponding average chlorinity in the ~18–20 ppt range. The salinity of the landlocked Dead Sea is an order of magnitude higher. **Table 2**

shows the 'average' concentrations of ionic constituents in open seawater of 35‰ salinity. From a corrosion viewpoint, all the ocean waters can be considered as sufficiently corrosive toward carbon steel, typically the most commonly used constructional material, such that corrosion control in some form or another is essential for extended structure and component life and functionality in most cases.

In terms of salt content, the 'average' seawater composition corresponds to ~3.5% NaCl solution. Thus, many researchers who do not have easy access to natural seawater often use this composition as a synthetic substitute. Others use artificial seawater solutions<sup>2</sup> that attempt to more closely mimic real seawater, at least in terms of dissolved salts. The chloride ( $\text{Cl}^-$ ) ion is considered to be the most aggressive specie in seawater, particularly for localized corrosion. Sulfate ( $\text{SO}_4^{2-}$ ) ions play an important

role in the activity of sulfate-reducing bacteria (SRB) which proliferate under anaerobic conditions, and can cause serious corrosion problems for certain materials and applications as discussed later in this section.

Calcium ( $\text{Ca}^{2+}$ ) and bicarbonate ( $\text{HCO}_3^-$ ) ions in seawater contribute toward calcium carbonate ( $\text{CaCO}_3$ ) scale formation, which is especially enhanced on heat transfer surfaces because of the inverse solubility of  $\text{CaCO}_3$  with temperature. Such scales can impede transport of DO to the metal surface, and hence, reduce general corrosion of active metals and the effects of seawater velocity so long as the scale is not dislodged. However, the scale reduces heat transfer, and can significantly increase the probability of localized (under-deposit) corrosion attack, particularly on materials with passive films that are susceptible to such conditions (e.g., 300-series stainless steels, aluminum alloys, nickel-copper alloys, etc.) in aerated seawater. Of course,  $\text{Ca}^{2+}$  and  $\text{HCO}_3^-$  are also critical species in the formation of undersea corals and protective shells by numerous marine organisms such as clams, oysters, barnacles, crabs, lobsters, star fish, urchins, and so on.

Organic matter necessary for biological processes contains carbon, oxygen, hydrogen, nitrogen, and phosphorus. Carbon, oxygen, and hydrogen (e.g., as polysaccharides and lipids) are available in abundance, but usable nitrogen and phosphorus compounds (primarily nitrates and phosphates) are generally limiting nutrients. The main sources of these latter nutrients include, river runoff into the sea, decaying organic matter, and upward water flow from deeper ocean areas. In littoral waters, these nutrients can reach very high concentrations where water runoff from land (e.g., in rivers) discharges large amounts of sewage and fertilizers from anthropogenic sources. Nutrient-rich waters encourage excessive plant growth, which depletes oxygen and kills animal life – a process known as eutrophication. An example of this is 'red tides,' which are associated with phytoplankton (algae) blooms.

Industrial waste from anthropogenic sources that is discharged into any body of water is technically a source of pollutants, which can consist of, for example, heavy metals and inorganic and organic compounds. The introduction of high levels of pollutants can alter the corrosivity of seawater toward certain materials, for example, copper-ion effects on aluminum alloys, sulfides and ammonia on copper alloys, sulfur compounds on steels, and so forth.

**Table 1** Salinity of various ocean waters expressed as approximate total dissolved solids ( $\text{mg l}^{-1}$  or ppm)

Seawater	Approximate TDS (ppm)
Arabian Gulf	47 000
Red Sea	43 000
Mediterranean Sea	41 000
Atlantic Ocean	36 000
Indian Ocean	35 000
Pacific Ocean	34 000
North Sea	33 000
Bering Sea	32 000
Black Sea	22 000
Caspian Sea	13 000
Baltic Sea	8 000
Dead Sea	322 000

**Table 2** Major ionic constituents in seawater of 35‰ salinity (35 000 ppm TDS)<sup>1</sup>

Ion	Concentration (ppm)
Chloride, $\text{Cl}^-$	19 353
Sodium, $\text{Na}^+$	10 760
Sulfate, $\text{SO}_4^{2-}$	2 712
Magnesium, $\text{Mg}^{2+}$	1 294
Calcium, $\text{Ca}^{2+}$	413
Potassium, $\text{K}^+$	387
Bicarbonate, $\text{HCO}_3^-$	142
Bromide, $\text{Br}^-$	67
Strontium, $\text{Sr}^{2+}$	8
Borate, $\text{B}_4\text{O}_7^{2-}$	4
Fluoride, $\text{F}^-$	1

### 2.18.2.2 Dissolved Gases

DO represents the most important species that controls the corrosion behavior of many materials in seawater, even more so than chloride. DO concentration is reported either as  $\text{ml l}^{-1}$  or  $\text{mg l}^{-1}$  ( $\text{ml l}^{-1} \times 1.429 = \text{mg l}^{-1}$ ). The primary factors that control DO content of seawater include temperature, salinity, biological activity, and mixing (flow). The inverse solubility of dissolved oxygen versus temperature and dissolved oxygen versus salinity is depicted in **Figures 1 and 2**, respectively. The DO concentration of the Dead Sea, which has a salinity of  $\sim 322$  ppt, is apparently  $\sim 0.1 \text{ mg l}^{-1}$ .

Oxygen dissolves in seawater either from the atmosphere and/or from plant photosynthesis, which is most prevalent over a depth  $\sim 100$  m. Thus, surface waters at normal atmospheric pressures tend to be saturated or supersaturated in oxygen, including the thin liquid environment in the splash zone. However,

quiescent flow conditions that favor algal growth and proliferation of decaying matter can reduce DO content markedly because of biological oxygen demand (BOD).

The principle reaction in seawater that controls corrosion is oxygen reduction. For any given DO concentration, the corrosion process is often strongly influenced by seawater velocity. This is discussed under corrosion mechanisms later in this chapter. The role of carbon dioxide is discussed in the following section. Other gases such as hydrogen sulfide and ammonia can be generated by bacteria from decaying matter and can influence corrosion of certain materials as discussed later.

### 2.18.2.3 Seawater pH

Clean surface seawater is typically slightly alkaline. This is related to the carbon dioxide ( $\text{CO}_2$ ) equilibrium with the atmosphere. Seawater contains bicarbonate

**Figure 1** Dissolved oxygen (DO) versus temperature in natural seawater of 35‰ salinity at 1 atm pressure.

**Figure 2** DO versus salinity in synthetic seawater at 20°C and 1 atm pressure.

( $\text{HCO}_3^-$ ) ions, carbonate ( $\text{CO}_3^{2-}$ ) ions, undissociated carbonic acid ( $\text{H}_2\text{CO}_3$ ), and dissolved  $\text{CO}_2$ . The pH is influenced by temperature,  $\text{CO}_2$  partial pressure (which affects carbonate in solution), photosynthesis, and to a lesser extent by boric acid. These factors interact to maintain the pH in a surprisingly alkaline range (8.1–8.3), and hence, seawater is said to be highly buffered. Hydrogen sulfide, for example, from sulfate-reducing bacterial (SRB) activity, can lower the pH considerably and affect the performance of certain materials.

#### 2.18.2.4 Calcareous Deposits

Calcium, bicarbonate, and magnesium in seawater are important constituents that can result in the formation of calcareous deposits on metal surfaces. Calcareous deposits form on cathodic surfaces and can slow down the corrosion process by inhibiting diffusion of DO and, consequently, its reduction at the metal surface. Calcareous deposit formation is particularly important when large, bare structures (e.g., steel offshore platforms) are cathodically protected in seawater. Without calcareous deposits, current demand for cathodic protection would remain at a high level, consequently, sacrificial anode life would be considerably reduced and the structure may not polarize to adequate protection levels. Calcareous deposit morphology and thickness are affected by current density at the cathode, seawater composition, temperature, and velocity.

#### 2.18.2.5 Temperature

Seawater temperature is also influenced by many geographical factors. Temperature generally decreases with depth. It also varies seasonally at the surface, ranging from  $\sim 35^\circ\text{C}$  at the equator to  $\sim -2^\circ\text{C}$  at the poles. Increasing temperature lowers solubility of dissolved gases and scale-forming calcium compounds such as calcium carbonate, but generally increases biofouling. All these factors can have a complex effect on corrosion behavior as discussed later in this chapter.

#### 2.18.2.6 Effect of Depth

Figures 3 and 4 illustrate how various parameters can vary with depth<sup>2</sup> and geographic location.<sup>3</sup> Generally, DO, temperature, and pH decrease steeply with depth over the first several hundred meters while salinity increases. Hydrostatic pressure increases with depth

while light penetration decreases. It has been postulated that the increase in DO at several 1000 m in the Atlantic Ocean is due to the flow of cold seawater through the ‘funnel’ in the north; but in the Pacific Ocean, this effect is prevented because of a minor flow through the Bering Strait.<sup>4</sup> It is important to recognize that the data shown in Figures 3 and 4, for example, are very site specific. Thus, quite wide variations in parameters can occur from one location to another, which can only be determined from actual measurements. Consequently, these variations can influence corrosion behavior of certain materials.

#### 2.18.2.7 Fouling, Macro- and Microorganisms

Fouling constitutes the attachment of macro- and microorganisms, most prevalent on stationary surfaces. Biofilms apparently start forming on all metallic and nonmetallic surfaces within hours of exposure to seawater.<sup>5</sup> Biofilms which are associated with organic matter and molecules (exopolymers) in seawater are colonized by various bacterial microorganisms. As the films become established, heavier slime formation is followed by attachment of macro species,<sup>6</sup> for example, barnacles, oysters, clams, sea squirts, and vegetable species such as seaweed, bryozoa, hydroids, and codium. The macrofouling species predominate in the tidal zone and can slow down diffusion of dissolved gases, and hence overall corrosion of certain materials. However, shielding of the surface can lead to local anaerobic conditions, anaerobic bacterial activity, and subsequently, localized attack. Some materials (e.g., copper-rich alloys) are more resistant but not entirely immune to macro fouling compared with other materials that foul copiously (e.g., carbon steel, stainless steel, titanium, and even nonmetallics).

#### 2.18.2.8 Effect of Velocity

Velocity can influence corrosion behavior in seawater in multiple ways. If the velocity is too low (quiescent conditions), solids may settle out, subsequently leading to under-deposit attack (e.g., on susceptible grades of stainless steel such as Type 410, 430, 304, 316, etc.). At intermediate velocities, such deposits may be suspended in the flow (once deposits have formed, much higher flow rates may be necessary for their removal than preventing settlement in the first place). As velocity continues to increase, biofilm and calcareous deposit formation diminishes. However,

**Figure 3** Variations in DO, temperature, pH, and salinity at a specific Pacific Ocean corrosion test site. Reproduced from Dexter, S.C.; Culberson, C. *Meter. Perform.* **1980**, 19(9), 23.

increased wall shear stress, turbulence, and impingement create conditions conducive for the removal of protective films on solid surfaces – thus, increasing the risk of erosion–corrosion of susceptible materials (e.g., carbon steel, copper-base alloys, aluminum-base alloys). At extreme velocities, even otherwise highly corrosion-resistant materials become increasingly susceptible to cavitation damage. Generally, for active

materials, increasing the velocity increases corrosion rate as more DO is transported to the metal surface. For passive materials, the enhanced diffusion of DO due to higher velocities is usually beneficial as long as the attack (e.g., crevice corrosion) has not been already initiated. Macroorganisms, calcareous deposits, and coatings generally reduce velocity effects, partly by slowing diffusion of oxygen to the metal surface.

However, at higher velocities these protective mechanisms may be negated as discussed earlier.

### 2.18.2.9 Seawater Resistivity

Seawater typically has low electrolytic resistivity (resistivity is reciprocal of conductivity) due to its significant dissolved salt content. Low resistivity generally corresponds to greater local cell action, larger anode–cathode interaction distances, and consequently, higher corrosion rates (particularly for active materials such as carbon steel), higher galvanic corrosion rates, and higher current output from cathodic protection anodes. Table 3 shows that resistivity decreases with increasing salinity and temperature; the resistivity values shown in Table 3 were converted from the conductivity data.<sup>7</sup> Thus, higher resistivities can be expected for seawater affected by fresh water outflows, for example, in coastal areas and for colder waters.

### 2.18.3 Corrosion and Protection Mechanisms

From a corrosion standpoint, chloride ions are considered to be the most aggressive constituent in seawater. The precise role of chloride in the corrosion

process is still not fully understood. For instance, chloride contributes to increased electrolytic conductivity by ion transport. Higher conductivity means that current between anodic and cathodic areas can flow over larger distances, for example, in galvanic couples; the magnitude of local cell currents can also be higher. Thus, the overall effect is typically higher general and/or localized corrosion rates. Corrosion attack at anodic areas is supported by reduction reaction(s) at cathodic sites – typically oxygen reduction in aerated seawater.

Corrosion products can provide some degree of protection if they impede oxygen diffusion to cathodic sites. Reduction in general corrosion rate of steel in seawater due to formation of corrosion products and macrofouling is illustrated in Figure 5.

Oxygen reduction is obviously a critical reaction for metallic corrosion in seawater. Deoxygenation of seawater is a recognized method of corrosion control for carbon steel, for example, in multistage flash distillation plants and water injection in offshore oil/gas production during secondary recovery. Thus, chloride ions are rendered relatively harmless in the complete absence of oxygen. Typical polarization curves for steel in aerated and deoxygenated seawater are shown in Figure 6. It is apparent that although the corrosion potential is nearly 400 mV more ‘active’ in the absence of oxygen, the corrosion rate is significantly lower when compared with aerated seawater.

Differences in oxygen levels between local areas produce potential differences that give rise to concentration cells – commonly referred to as differential oxygenation or differential aeration cells. The low oxygen or anoxic (oxygen-free) area becomes anodic because of its more active (electronegative) potential; conversely, the area of higher oxygen becomes

cathodic because of its less active (more electropositive) potential. This is usually demonstrated in the laboratory by setting up a partitioned cell in which one-half is aerated and the other half is deaerated with a steel electrode immersed in each half. The measured open-circuit potentials and couple current flow direction indicates the afore-mentioned anode/cathode relationship. However, as noted by Tomashov,<sup>8</sup> actual corrosion rate of the steel electrode in the aerated half of the cell is greater in chloride solutions, despite being the cathode in the differential-aeration macrocell, than in the deaerated half. This apparent contradiction is due to enhanced microcell action in solutions containing chloride that prevents anodic passivation of the steel. Lower corrosion rates of steel piles in the mud

zone (low oxygen environment) relative to the submerged zone above it (aerated environment) were cited as a practical manifestation of this apparently anomalous behavior. In other words, in seawater, chloride ions and associated high conductivity generates microcell activity that overrides the differential-aeration macrocell. In environments where steel can 'passivate,' for example, chloride-free waters or soils, the classical differential-aeration mechanism is operative.

In anaerobic seawater environments, the oxygen reduction reaction is negated. However, high corrosion rates observed under anoxic conditions have been attributed to microbiological activity, in particular, sulfate-reducing bacteria (SRB, e.g., *Desulfovibrio*

**Figure 5** Decrease in general corrosion rate of carbon steel in quiescent seawater associated with development of corrosion products and macrofouling.

**Figure 6** Polarization curves for carbon steel in aerated versus deaerated seawater.

*desulfuricans*). These bacteria reduce sulfate to sulfide under favorable conditions.<sup>9–11</sup>

While SRB can influence corrosion in anaerobic environments, propagation of corrosion attack is generally most prevalent under conditions of alternate exposure to anaerobic and aerobic environments. In principle, an impervious sulfide film covering the entire metal surface may be protective. However, in practice, such films are rarely impervious and/or continuous. Thus, corrosion at small exposed areas of the substrate is accelerated as the sulfide film serves as a large cathodic surface. The adverse effect of sulfide on corrosion of copper heat exchanger alloys is well known and discussed later in this chapter. Bacteria other than SRB can also influence corrosion behavior in seawater.

As discussed earlier, calcareous deposits form on cathodic surfaces. Although enhanced under cathodic protection conditions, such deposits can also form at cathodic areas associated with corroding surfaces. Hydroxyl ion generation by the oxygen reduction reaction at the cathodes increases the pH at the metal surface. The increase in pH alters the equilibrium, which can result in precipitation of calcium carbonate scale.

Under cathodic overprotection conditions, formation of magnesium hydroxide is favored.

Adherent calcareous deposits slow the diffusion of oxygen to the metal surface. For immersed surfaces, this implies polarization of the oxygen reduction reaction, and hence a decrease in cathodic protection

current demand or a decrease in general corrosion rate when there is no cathodic protection.

Calcareous deposits play a critical role in cathodic protection of bare metal structures in seawater. Early pioneering work by Cox generated several patents, which described the ‘best’ current density ranges to produce the most protective calcareous deposits<sup>12,13</sup> that were referred to as ‘electrocoating.’ Over the years, many research efforts have been pursued for a better understanding and optimization of calcareous deposits.<sup>14–24</sup> It has been shown that the deposits are affected by many variables that include current density, potential, seawater velocity, temperature, and chemistry.

For example, **Figure 7** shows current densities associated with calcareous deposits formed in synthetic seawater at several potentiostatically-controlled protection potentials in 50 h. Variation of deposit morphology with protection potential is illustrated in the SEM photomicrographs in **Figure 8**. At  $-1100$  mV (SCE), the deposits consisted predominately of  $\text{CaCO}_3$  (aragonite) and a trace of  $\text{Mg}(\text{OH})_2$  (brucite). Although the deposits were thick, they were poorly adherent and not very protective since the current density did not decrease significantly. More adherent and protective deposits, composed primarily of  $\text{CaCO}_3$  (aragonite), were formed at  $-800$ ,  $-900$ , and  $-1000$  mV (SCE). At  $-750$  mV (SCE), complete cathodic protection was not attained, and the deposits comprised a mixture of  $\text{CaCO}_3$  and iron corrosion products ( $\text{Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$ ). Data are not included in **Figures 7 and 8** for deposits formed at  $-1200$  mV (SCE); however, the current density was  $>10^4$  mA m<sup>-2</sup>, the deposits were thick, gelatinous, mainly  $\text{Mg}(\text{OH})_2$ , and nonprotective. In practice,

**Figure 7** Current density versus time for clean steel at various protection potentials versus SCE.

**Figure 8** Morphology of calcareous deposits formed at various potentials in synthetic seawater in 50 h.

many impressed current cathodic protection systems operate at constant current. As calcareous deposits form under constant current conditions, the current density increases at local areas, the potential of the protected metals shifts in the negative direction, and the morphology of the calcareous deposits changes. From a research viewpoint, it is easier to study the formation of, and protection afforded by, calcareous deposits under potentiostatic conditions rather than constant current conditions. Moreover, cathodic protection from well-designed sacrificial-anode systems, which are more common in seawater applications, approximates potentiostatic conditions, that is, anode output decreases as calcareous deposits are formed. However, Humble<sup>14</sup> has shown that the Ca/Mg ratio in calcareous deposits decreases with increasing current density as illustrated in Figure 9. Surprisingly, it has been found that  $\text{Mg}^{2+}$  ions in seawater inhibit  $\text{CaCO}_3$  crystal nucleation and precipitation.<sup>25</sup> However, the greater concentration of  $\text{Mg}^{2+}$  in open seawater compared to  $\text{Ca}^{2+}$  assures that  $\text{CaCO}_3$  will precipitate as aragonite.<sup>26</sup> In other natural waters, precipitation of  $\text{CaCO}_3$  as calcite is favored because the concentration of  $\text{Ca}^{2+}$  is usually much greater than that of  $\text{Mg}^{2+}$ .

Table 4 provides some quantitative and qualitative data on calcareous deposit properties relative to cathodic protection current densities. The solubility of  $\text{CaCO}_3$  decreases with increasing temperature, while that of  $\text{Mg}(\text{OH})_2$  increases. Thus, precipitation of  $\text{CaCO}_3$  is favored in warm seawater, and that of  $\text{Mg}(\text{OH})_2$  in colder seawater. This has been postulated as one possible explanation of higher current density requirements for cathode protection of steel structures in colder seawater. It is apparent that calcareous deposit formation involves complex phenomena; thus, ideally, characterization and optimization of

calcareous deposits for specific applications are best performed locally, *in situ*.

It is generally accepted that protection for materials such as aluminum alloys, titanium alloys, stainless steels, and nickel alloys is conferred by surface passive oxide films. In other words, these materials possess active-passive characteristics. In seawater, active corrosion is suppressed if the material exhibits passive behavior. The air-formed oxide films are thin (typically  $<10$  nm). The composition of the base metal, heat treatment, surface cleaning, surface finish, and the exposure environment are among the primary factors that determine the stability of the passive film. There is some evidence that adsorbed species from the exposure environment, for example, oxygen, contribute to the properties of the passive film.<sup>28</sup>

The most deleterious species toward passive films in seawater is chloride. Film breakdown and rehealing is a dynamic process. However, under certain conditions rehealing may not occur after corrosion has initiated at local areas. This can lead to propagation of attack and high rates of localized corrosion. A classical case of this is crevice corrosion of susceptible stainless steels, for example, under gaskets, under O-rings, at threaded joints, under silt and macrofouling deposits, and so on. Previously, this type of attack was ascribed to oxygen concentration cells, that is, absence of oxygen in the crevice and plentiful supply outside the crevice. However, the modern view is a little more complex. Crevice corrosion has been modeled mathematically and experimentally in a number of ways.<sup>29–33</sup> Deeper and tighter crevices are more susceptible to both the initiation and propagation of crevice corrosion. Metal-to-nonmetal crevices are generally tighter than metal-to-metal crevices because of the easier deformation of the nonmetal. However, metal-to-metal crevices, although less tight, may be equally susceptible to attack because both metal surfaces can contribute metal ions for hydrolysis. In dissimilar alloys, crevice attack on the more susceptible metal occurs first. As the crevice electrolyte becomes more aggressive by the autocatalytic process, crevice corrosion can initiate subsequently on the more resistant alloy.<sup>34</sup>

Electrochemical measurements have been used to demonstrate potential ennoblement and increased cathodic kinetics on passive surfaces covered by biofilms in seawater.<sup>35,36</sup> It has also been shown that biofilms are more prevalent in warm seawater, and hence decrease crevice corrosion initiation time compared to cold seawater. Above a threshold temperature

**Figure 9** Ca/Mg ratio in calcareous deposits formed in seawater at various cathodic protection current densities over 3 months. Reproduced from Humble, H. A. *Corrosion* **1948**, 4(7), 358–370.

**Table 4** Calcareous deposits properties relative to cathodic protection current densities

Initial current density (mA m <sup>-2</sup> )	Duration (days)	Calcareous film formed	Current density for continued protection (mA m <sup>-2</sup> )
2000	1	Soft with high Mg content	20–30
1000	2–3	Fairly hard	20–30
500	5–6	Hard, mainly calcareous	20–30
200	20–30	Medium thickness, hard	30–40
100	60–90	Medium thickness, hard	40
60	180	Light, hard	40–50

of  $\sim 50^\circ\text{C}$ , crevice corrosion susceptibility in natural seawater apparently decreases.<sup>32</sup> It has been hypothesized that this behavior is due to reduced microbial activity in biofilms above such temperatures. This is analogous to reduction in crevice corrosion propensity in seawater treated with biocide, for example, 2 ppm residual chlorine, which inhibits biofilms and microbial activity. Crevice corrosion observed at elevated temperatures where biofilms are absent and microbial activity diminished must be explained by other mechanisms. For example,

crevice corrosion of titanium is considered to occur at temperatures  $>70^\circ\text{C}$ .

Empirical data and experience indicate that some alloys are clearly much more resistant to crevice corrosion than others under the same crevice geometry and seawater conditions. It has been postulated that this is due to more stable passive films formed as a result of certain minimum combinations of alloying additions, primarily Cr, Mo, and N. Interestingly, it has been shown that hydrolysis of  $\text{Cr}^{3+}$  and  $\text{Mo}^{3+}$  produces the lowest pH values for the crevice electrolyte.<sup>37</sup> This appears to be the case when insufficient Cr and Mo (and possibly other synergistic elements) are present on the alloy surface to produce a passive film that prevents hydrolysis, acidification, and anodic dissolution. It has been suggested that addition of N to stainless steels can produce ammonium ( $\text{NH}_4^+$ ) ions that raise the pH and effectively neutralize any acidification due to hydrolysis in the crevice.<sup>38</sup>

It is often stated that increasing oxygenation of seawater (e.g., by increasing flow rate) alleviates crevice corrosion. This is based on the widely held view that higher flow rates minimize biofilm attachment and allow easy access of oxygen which is necessary to maintain passivity. That would be the case if oxygen was able to reach all areas of the metal (including the crevice) quickly. In fact, increasing oxygen supply worsens the situation because the oxygen-reduction cathodic reaction is enhanced by depolarization on surfaces outside the crevice, while oxygen diffusion

into the crevice and neutralization of the acidic conditions within the crevice, both necessary for repassivation, remain severely restricted by the crevice geometry. In other words, the trapped acidic electrolyte in the crevice and lack of oxygen ingress keeps the crevice very active, while the area outside the crevice serves as an efficient cathode. Moreover, the rate of attack within the crevice can be very severe since the ratio of the cathode (area outside the crevice) to anode (area inside the crevice) is often quite large in many components in seawater immersion applications. This is illustrated by the example in [Figure 10](#).<sup>39</sup>

Another poorly appreciated fact is the behavior of active-passive metals in deaerated solutions. As stated previously, materials such as stainless steels depend on the formation and maintenance of a passive film on the alloy surface exposed to seawater. A widely held but mistaken view is that deaerated seawater is detrimental because oxygen is unavailable to sustain passivity. However, the fact of the matter is that removal of oxygen from seawater is not normally deleterious toward such alloys because oxygen reduction is the primary cathodic reaction that controls the propagation of pits and/or crevice attack. This has been demonstrated experimentally. Since the seawater pH is near-neutral, the alternative hydrogen-discharge cathodic reaction is negligible. Thus, even if oxygen is unavailable to maintain passivity, corrosion of active-passive alloys in seawater will be imperceptible unless some other cathodic reaction is viable. Even with anaerobic bacteria active under anoxic conditions, corrosion damage occurs predominately when subsequent exposure to aerated conditions occurs.

### 2.18.3.1 Galvanic Corrosion

[Figure 11](#) is a depiction of the typical galvanic series of metals and alloys in seawater that is widely available to engineers. Unfortunately, the severe limitations of adequately predicting galvanic corrosion from such a series alone are commonly underestimated. The series basically represents a ranking of metals and alloys according to their free corrosion potentials in a given environment (in this case, flowing natural seawater at ambient temperature). For a given metal or alloy, the ranking can be influenced by a number of variables, for example, temperature, flow rate, fouling, chlorination, crevices, oxygen content, and so forth. The series provides only qualitative information on likely galvanic corrosion if two dissimilar materials in the series are electrically coupled in the environment. Corrosion of the anodic material (i.e., one with a relatively more electronegative corrosion potential) is likely to be accelerated, and corrosion of the cathodic (i.e., one with a relatively more electropositive corrosion potential) material is slowed or stopped. However, the degree of galvanic interaction cannot be determined quantitatively from the series alone. If Ohm's law applied, then the amount of galvanic attack would be a function of the potential difference between the two dissimilar materials and the total circuit resistance. However, polarization behavior of the materials and their relative area ratios have been found to be much more significant than the potential difference. The example [Figure 12](#) shows that the potential difference between titanium and steel in seawater is nearly double that of copper versus

**Figure 10** Maximum depth of crevice attack on 17-Cr stainless steel in seawater versus exposed cathodic (passive) surface area outside crevice. Adapted from Ellis, O. B.; LaQue, F. L. *Corrosion* **1951**, 7(11), 362.

**Figure 11** Typical galvanic series of metals and alloys in flowing natural seawater. Solid bars represent active corrosion potentials for otherwise passive alloys.

steel. However, for the same anode/cathode area ratio, the galvanic current density for the titanium/steel couple (and hence expected corrosion rate of steel) is nearly nine times lower compared to the copper/steel couple. This behavior is due to the polarization of the cathode, for example, oxygen reduction on titanium is less efficient than on copper. Polarization is influenced by surface films. For example, biofilms on metal surfaces generally enhance reduction reactions and hence galvanic corrosion in certain couples.<sup>41</sup> Although chlorination is used for biofouling control (e.g., to maintain heat transfer), low levels have also been found to reduce galvanic corrosion, for example, of copper alloys coupled to more noble alloys, because reduction reactions are polarized appreciably.<sup>42,43</sup> If

calcareous deposits form on cathodic surfaces, they hinder oxygen diffusion, and hence can reduce galvanic corrosion effects.

It is generally accepted that galvanic attack on the anodic member in a dissimilar metal couple intensifies as the cathode/anode area ratio increases. However, geometry and spatial disposition of the anode and cathode can also play an important role. For example, in a retubed seawater heat exchanger, titanium tubes represent a large surface area with respect to the original copper-nickel tube sheet. This generally results in high galvanic corrosion rate of the latter. In a plate-type heat exchanger, the surface area of the titanium plates is very large compared to say the adjoining copper-nickel piping. However, galvanic corrosion of the latter is not usually

**Figure 12** Polarization curves for carbon steel (anode) versus copper (cathode) and titanium (cathode), illustrating galvanic current density depends on polarization behavior rather than galvanic couple potential difference. Adapted from LaQue, F. L. *Marine Corrosion: Causes and Prevention*; Wiley, 1975; p 195.

significant because the tortuous pathways between the titanium plates represent a high electrolytic resistance.

The galvanic series only relates to consideration of two materials at a time in a galvanic couple. In many practical applications, multiple metals may be involved. For example, if aluminum, steel, copper, and titanium components are all coupled in a system, the galvanic series only indicates that titanium would be cathodic and aluminum would be anodic with respect to each other. The galvanic series would not indicate whether steel and copper would behave anodically or cathodically in the overall system. This could only be determined after measuring the mixed potential (when all the subject metals are electrically coupled).

Another widely misunderstood aspect of galvanic corrosion is the interaction of graphite with other metals. Because of its typically most noble position in the galvanic series, it is often misstated that graphite forms adverse galvanic couples with all metals. Graphite (and graphite-containing materials) can certainly accelerate corrosion of metals such as copper, steel, and aluminum, especially for large cathode/anode area ratios. However, graphite is galvanically compatible with titanium, most Ni–Cr–Mo alloys, and many stainless steels. For example, attack observed on stainless steels in contact with graphite gaskets is often incorrectly attributed to galvanic corrosion. However, practical experience indicates that such attack (and of similar magnitude) is in fact due to crevice corrosion which occurs even when the graphite is replaced by a nonconductive gasket material.<sup>44</sup>

## 2.18.4 Carbon Steels

Carbon steels are widely used in seawater applications because of their ready availability, extensive range of mechanical properties, ease of fabrication, and usually lowest initial cost. However, carbon steels are very susceptible to corrosion in marine environments, and hence require some form of corrosion control. As stated earlier, corrosion rate is affected by a complex interaction of factors that include DO, temperature, depth, flow rate, and microbiological activity.

**Figure 13** illustrates the typical corrosion profile of steel piling subjected to various marine zones. The highest corrosion rate in the splash and spray zone is attributed to constant wetting that produces a thin film of seawater through which oxygen diffuses readily. The high corrosion rate, constant wetting conditions, and the mechanical effects of splashing preclude development of protective corrosion products. Even if coatings are applied prior to installation, they are virtually impossible to maintain in this zone. However, successful long-term protection has been achieved with metallic sheathing<sup>46,47</sup> (e.g., using alloys such as NiCu alloy 400 and 90/10 CuNi). Nonmetallic wraps have also been used for protection in the splash zone.<sup>48,49</sup>

In the tidal zone, the structure is exposed to alternate immersion. The lower general corrosion rates in this zone are ascribed to oxygen shielding by macrofouling. However, localized attack can be aggressive if SRB activity under anaerobic macrofouling

**Figure 13** Corrosion profile of steel piling exposed to various zones in a natural marine environment for 5 years. Reproduced from Humble, H. A. *Corrosion* **1948**, 5(9), 23–28.

conditions is high. A particularly severe form of attack known as ‘accelerated low water corrosion (ALWC)’ afflicts steel sheet piling in some ports and harbors at areas just above the lowest astronomical tide.<sup>50–52</sup> The phenomenon is not fully understood presently. However, empirical evidence suggests a strong influence of microbiological organisms, especially SRB possibly synergized by acid producing bacteria; corrosion penetration can exceed  $1 \text{ mm year}^{-1}$  on a given steel surface. Apparently, structures affected by ALWC are usually exposed to tidal and brackish waters.

As discussed earlier, reduction of DO is the primary cathodic reaction controlling corrosion of steel in aerated marine environments. Although oxygen solubility decreases with increasing temperature, corrosion of steel immersed in seawater generally increases with temperature and with flow rate. The data in **Table 5** illustrate the increase in corrosion rate of steel in warmer seawater during the summer months despite the lower oxygen content. **Figure 14** depicts increase in corrosion rate with flow velocity in ambient temperature seawater in the absence of significant corrosion products.<sup>53</sup> Adherent corrosion products can diminish the effect of flow. However, above a critical wall shear stress, corrosion products are prevented from forming and existing ones removed by erosion.

The corrosion rate of steel, based on mass loss, in quiescent seawater is typically on the order of  $\sim 0.13 \text{ mm year}^{-1}$  after several years of exposure. A 5-year worldwide seawater corrosivity test program

**Table 5** Seasonal variations in corrosion rate of steel in natural seawater at  $\sim 0.2 \text{ m s}^{-1}$

Period	Ave temp (°C)	Ave dissolved oxygen (ppm)	pH	Ave corrosion rate ( $\mu\text{m year}^{-1}$ )
Jan–Mar	10.5	9.2	8.0	100
Apr–Jun	22.4	6.9	8.0	130
Jul–Sep	27.2	6.0	8.0	140
Oct–Dec	14.1	8.2	8.1	110

indicated that local conditions can exert a strong influence on corrosion rate and types of attack.<sup>54</sup> In some cases, pitting rates were much higher than general corrosion rates, as illustrated by the data in **Figure 15**. Complete localized penetration of the 6-mm plate thickness occurred on some, but not all test panels at specific exposure locations. This type of accelerated localized attack resulting in large, round pits has been attributed previously to sea urchins<sup>55</sup> – which apparently ‘scrub’ corrosion products, and thus expose fresh metal surface to enhanced corrosion rate. Extensive data analysis and modeling on corrosion of steel in seawater have been performed by Melchers<sup>56</sup>; the primary conclusions were that velocity affects corrosion in the early stages until marine fouling and corrosion products develop – thereafter, influence of fouling thickness is significantly reduced. DO and temperature rather than depth *per se* affect corrosion; for a given exposure period, test specimens first exposed during autumn and winter exhibited less corrosion than those first exposed in spring and summer.

**Figure 14** Corrosion rate of clean carbon steel in ambient temperature flowing natural seawater on 38 days. Reproduced from Oubner, R.; Beech, I. In *Corrosion/1999*; NACE International: Houston, TX, 1999; Paper No. 99318.

**Figure 15** Mass loss corrosion rate and maximum depth of pitting attack on carbon steel in seawater at 14 worldwide test locations. For each location, the bars represent (from the left) 0.5, 1, 3 and 5-year exposures. NJ – New Jersey, NC – North Carolina, FL – Florida, TX – Texas, CA – California, HI – Hawaii, AU – Australia, JA – Japan, IT – Italy, DE – Denmark, ST and BM – Sweden, EN – England. It is commonly believed that macrofouling reduces oxygen transport and, consequently, overall corrosion rate of steel in seawater. However, data from tests indicate similar corrosion behavior for carbon steel in filtered and unfiltered seawater – suggesting that microfouling may be more important than macrofouling in controlling corrosion behavior. This appears

contradictory to the view that biofilms enhance the oxygen reduction reaction, for example, in microbiologically influenced corrosion of stainless steels.

In shallow immersion, pitting depths on carbon steel can be an order of magnitude higher than general corrosion rates calculated from mass loss as illustrated in [Figure 16](#).<sup>57</sup> Determination of pitting rates

**Figure 16** Corrosion of carbon steel in natural seawater. Average penetration calculated from mass loss of six replicate test panels – slope corresponds to  $\sim 0.07 \text{ mm year}^{-1}$  corrosion rate; average pit depth is the mean of 60 measured pits, five deepest pits on each surface of six test panels. Reproduced from Southwell, C. R.; Alexander, A. L. *Mater. Prot.* **1970**, 9(1), 14–23.

can be an onerous task. A common but mistaken practice involves measuring the maximum or average pit depth and calculating a pitting rate. There are a number of flaws with this approach. First, pitting is not linear with time, especially for long-term exposures in seawater. Second, the data are usually based on measuring different pits on different test samples, that is, specific pits are not monitored as a function of time owing to the obvious experimental shortcomings of this approach. Pitting is a statistical process; the number, size, and locations of pits on a given metal surface can vary over a wide range. Thus, computing pitting rates from limited data, and assuming linear growth rate with time is fraught with problems.

**Figure 17** shows the general corrosion rate of carbon steels exposed for 1 year and DO content as a function of seawater depth.<sup>58</sup> It is apparent that the corrosion profile closely follows that of the oxygen concentration. The following relationship derived from linear regression analysis<sup>59</sup> indicates a greater dependence on oxygen content compared to temperature:

$$\text{Corrosion rate } (\mu\text{m year}^{-1}) = 21.3 + 25.4[\text{O}_2(\text{ml l}^{-1})] + 0.356[T(^{\circ}\text{C})]$$

Other data have indicated more complex corrosion behavior. For example, in unpolluted seawater, corrosion rate was dependent on oxygen content, whereas in polluted seawater, temperature had a greater influence.<sup>60</sup> Polluted seawater typically has the following characteristics (compared to unpolluted seawater):

lower oxygen content, lower pH, higher sulfide and sulfate-reducing bacteria concentrations, and higher ammonia content. Corrosion data suggest that at similar temperatures, the effect of lower oxygen content in polluted seawater is offset by the presence of pollutants,<sup>60</sup> especially sulfides.

Under immersion conditions, low alloy steels behave fairly similar to carbon steels. Small amounts of alloying additions do not evidently alter the corrosion rate of steel significantly in seawater. However, as the alloy content is increased further (e.g.,  $>5 \text{ wt\%}$ , especially Cr addition), a reduction in general corrosion rate is often replaced by deep, localized pits. It has been reported that low-alloy steels can cause galvanic corrosion of plain carbon steels despite a small difference in their corrosion potentials.<sup>61</sup>

Higher strength carbon steels are susceptible to hydrogen embrittlement (HE) in seawater, especially when polarized to excessively negative potentials. Factors that affect the susceptibility of steels in seawater to HE include yield strength (which is influenced by composition and heat treatment), electrochemical potential, and pollutants (especially sulfide). In general, susceptibility increases with increasing yield strength. High-strength steels are generally considered to be those with  $\text{YS} > 700 \text{ MPa}$ . Steels with  $\text{YS} < 700 \text{ MPa}$  are generally considered resistant to hydrogen embrittlement. Since alloying additions affect yield strength, it is difficult to delineate their influence on HE behavior. However, limited data<sup>62</sup> on steels of varying compositions but similar yield strengths indicate negligible

**Figure 17** Corrosion rate of carbon steel exposed for 1 year and DO concentration versus seawater depth ( $\text{DO ml l}^{-1} \times 1.429 = \text{mg l}^{-1}$ ); note similarity in profiles versus depth. Reproduced from Reinhart, F. M. *Corrosion of Metals and Alloys in the Deep Ocean*, Technical Report No. R-834, Civil Engineering Laboratory, Port Hueneme, CA, 1976; p 14.

effects of S or P (each  $<0.03\%$ ), Si or Cr (each  $<2.1\%$ ), Mo ( $<1.2\%$ ), and Co ( $<3\%$ ). Detrimental effects were indicated for C ( $0.3\text{--}0.4\%$ ), Mn ( $0\text{--}3\%$ ), and slightly deleterious for Ni ( $>6\%$ ). Tempering or aging heat-treatments at higher temperatures lower yield strengths and hence typically increase HE resistance. Ultra high-strength steels (e.g., with  $\text{YS} \geq \sim 1400$  MPa) can suffer HE even in distilled water. Elevated temperatures increase crack growth rates, probably as anodic dissolution rate increases, following Arrhenius behavior.<sup>63</sup>

Polarization of high-strength steel to more noble potentials than the free corrosion potential can markedly increase HE propensity as indicated by significantly shorter time to failure. Cathodic polarization to a narrow potential range (e.g.,  $-0.8$  to  $-0.9$  V SCE) is generally beneficial since anodic dissolution processes are stifled. However, cathodic polarization to more active potentials (especially more negative than  $-1$  V, SCE) again lowers cracking resistance. Pollutants, in particular sulfur-containing species, have been found to increase susceptibility to HE.

Carbon steel has been used extensively in the past for construction of flash chambers in thermal desalination plants. In principle, the corrosion rate should be negligible if DO is completely stripped from the seawater used in the process. However, in practice, it is very difficult to deoxygenate the seawater fully. Typically, oxygen concentration is reduced from ppm to ppb levels. However, increasing temperature has a far greater effect on corrosion than low oxygen levels. For example, data from a thermal desalination pilot-plant test revealed that even at a 100 ppb DO level and seawater flow-rate of  $\sim 1.7 \text{ m s}^{-1}$ , the corrosion rate of carbon steel doubled from  $0.3 \text{ mm year}^{-1}$  at  $81^\circ\text{C}$  to  $0.6 \text{ mm year}^{-1}$  at  $120^\circ\text{C}$ .<sup>64</sup> Oldfield and Todd<sup>65</sup> developed the following expression for calculating corrosion rate:

$$\text{Corrosion rate (mm year}^{-1}\text{)} =$$

$$(0.0117 \times C_o \times U_o^{0.9}) / Pr^{0.75}$$

where  $C_o$  is bulk concentration of oxygen in moles  $\text{cm}^{-3}$ ,  $U_o$  is bulk flow rate in  $\text{cm s}^{-1}$ , and  $Pr$  is the

Prandtl number (defined as ratio of kinematic viscosity,  $\nu$ , to diffusion coefficient,  $D$ ). The predicted corrosion trends were in good agreement with previously published field and test data; lower actual corrosion rates in the field were attributed to presence of corrosion products and scaling.

Millscale on steel surfaces is cathodic to the substrate. While the general corrosion rate of steel, based on mass loss data, may not appear significantly different, the presence of millscale can produce deep pitting by galvanic action due to the adverse cathode (millscale) to anode (exposed steel) area ratio.

## 2.18.5 Cast Irons

The initial corrosion behavior and corrosion rates of unalloyed gray and ductile cast irons in seawater are similar to those of carbon steels. However, in gray cast irons, as corrosion progresses, dissolution of the ferrite phase exposes increasing the amounts of the flake graphite network. This dealloying phenomenon is known as graphitic corrosion. It is commonly but incorrectly referred to as graphitization – which is really a metallurgical term used to describe decomposition of iron carbide ( $\text{Fe}_3\text{C}$ ) to iron (Fe) and graphite (C) at elevated temperatures. At low velocities, the iron corrosion products are often ‘trapped’ by the flake graphite network. In such cases, visual inspection can greatly underestimate material degradation because reduction in section thickness is not apparent. Ultrasonic inspection and/or destructive examination are usually necessary to monitor graphitic corrosion before catastrophic failure occurs.

Graphitic corrosion may advance to a stage where it can induce galvanic corrosion of other materials coupled to the cast iron. For example, initially steels are galvanically compatible with gray cast iron, while copper alloys are cathodic. However, graphitic corrosion of the cast iron can eventually generate or reverse the galvanic couple where the exposed graphite behaves cathodically to steels and copper alloys and accelerate their dissolution by galvanic action.<sup>66</sup> Graphitic corrosion and its consequences are not a major problem with ductile irons because the graphite is present as discrete nodules instead of a flake graphite network.

Addition of  $\sim 20\%$  Ni to cast iron increases toughness and shock resistance. However, the austenitic microstructure is still susceptible to graphitic corrosion, if the graphite is present in the flake

form. Depending on alloy composition, small Mg additions (e.g.,  $\sim 0.1\%$ ) during production convert the flake graphite to nodular form. This significantly increases the tensile strength, impact resistance, and graphitic corrosion resistance. Corrosion rates of austenitic cast irons (commonly referred to by a trade name, NiResist<sup>®</sup>) in seawater are often an order or magnitude lower than gray or ductile irons. The benefit of increasing Ni content in the cast iron is particularly notable for erosion–corrosion resistance in seawater at high velocities as illustrated by the data in Table 6. Sporadic stress corrosion cracking (SCC) problems observed in austenitic cast iron seawater pumps have been attributed to improper stress-relief heat treatment.<sup>67</sup>

## 2.18.6 Stainless Steels

The addition of  $>11\%$  Cr to Fe generates a Cr- and Fe-containing passive oxide film on the metal surface. There is a very marked reduction in general corrosion rate in seawater compared to carbon steel or low alloy steels. However, the stainless steels are highly susceptible to localized corrosion unless much more Cr and/or other alloying additions such as Mo, N, and Ni are also present. Thus, determination of general corrosion rates of stainless steels in seawater from weight loss results can be misleading because most of the metal dissolution is typically associated with pitting and crevice corrosion.

There are several hundred commercial grades of stainless steels, with widely ranging compositions and properties. Obviously, a large number of grades are unsuitable for seawater applications. Typically, stainless steels are divided into several broad classifications, *viz.* martensitic, ferritic, austenitic, superaustenitic, duplex, superduplex, and precipitation hardening

**Table 6** Effect of increasing Ni content in cast irons on erosion–corrosion behavior in seawater at  $8 \text{ m s}^{-1}$  at  $28^\circ\text{C}$  for 60 days

Alloy	% Ni content	Ave corrosion rate ( $\text{mm year}^{-1}$ )
Cast iron	–	6.9
2% Ni cast iron	2	6.1
Type 1 Ni-Resist	13.5–17.5	0.74
Type 2 Ni-Resist	18–22	0.79
Type 3 Ni-Resist	28–32	0.53

Source: Shreir, L. L., Ed. *Corrosion*; Newnes Butterworths, 1979; Vol. 1, pp 3–106.

(PH). Even within each classification, there can be a wide range of compositions.

Martensitic stainless steels are susceptible to pitting, crevice corrosion, SCC, and hydrogen embrittlement (especially under cathodic protection) in seawater.

High-Cr ferritic grades, such as Type 29-4C (29Cr-4Mo), are considered to have much greater resistance to localized corrosion compared to more leaner grades such as Type 430 (17Cr). Ferritic grades are resistant to chloride stress corrosion cracking ( $\text{Cl}^-$  SCC), but susceptible to hydrogen embrittlement, especially when subjected to cathodic protection, unintentional or otherwise.

Despite their popularity, particularly for marine atmospheres, many austenitic grades (such as many of the 300-series) are unsuitable for seawater service; unfortunately, they are often selected because of their attractive mechanical and welding properties, that is, without a complete understanding of their limitations, especially corrosion resistance. They are susceptible to  $\text{Cl}^-$  SCC; susceptibility trend decreases with increasing Cr or Cr + Ni content. They are resistant to hydrogen embrittlement except in the severely cold-worked condition. Type 304 is highly susceptible to pitting corrosion in seawater; Type 316 is more resistant due to the Mo addition but certainly not immune. The biggest limitation of these grades is their high propensity to crevice corrosion, for example, under gaskets, O-rings, washers, sleeves, macrofouling deposits, silt, and so on which are discussed later. Superaustenitic grades have higher alloy content ( $\sim 20\%$  Cr,  $25\%$  Ni, and  $\sim 6\%$  Mo, or more) for increased resistance to crevice corrosion; their higher Ni content also enhances resistance to SCC.

In seawater, the localized corrosion resistance of duplex stainless steels is similar or slightly better than many austenitic grades. They are slightly magnetic and susceptible to hydrogen embrittlement, for example, under cathodic over-protection conditions, or in the presence of hydrogen sulfide. Superduplex stainless steels have higher Cr and nitrogen contents (e.g., alloy 2705; 27Cr-5Ni-3Mo-0.2N), which improve corrosion resistance notably, but does not make them immune under all conditions. They are much more resistant to chloride SCC than austenitic stainless steels.

PH stainless steels are susceptible to pitting, crevice corrosion, SCC, and hydrogen embrittlement (especially under cathodic protection) in seawater.

The highly-oxygenated thin liquid film environment, and absence of biofouling in the splash zone

represent conditions under which stainless steels generally perform well at ambient temperatures and if critical crevices are not present. Leaner compositions may develop superficial rust staining. Stainless steel sheathing fabricated from 300-series austenitic stainless steel (e.g., Types 304 and 316) has been successfully used for long-term splash-zone protection at ambient temperatures.

The leaner grades of stainless steel are susceptible to localized attack under biofouling attachments that usually proliferate in the intertidal zone. **Figure 18** shows classical crevice corrosion of Type 304 stainless steel under barnacles.

The data in **Table 7** show localized corrosion penetration for several stainless steels after 16 years exposure in the intertidal and full immersion zones in Panama.<sup>69</sup> There was complete perforation of the 6-mm thick plate material by localized corrosion for all the grades tested under full immersion conditions. In the intertidal zone, the martensitic Type 410 material was also completely perforated, while the deepest pits on the other three grades ranged from  $\sim 1$  to  $\sim 3$  mm. Type 304 stainless steel pits in seawater like Type 302 and Type 321 (Type 321 is an analog of Type 304L, but stabilized with Ti for averting sensitization in lieu of lowering the carbon content). Attack typically initiates under biofouling attachments and at cut edges where inclusions in the material are exposed prominently. The acidic environment generated in the pits by metal-ion hydrolysis often leads to subsurface attack in the form of tunneling. On stationary structures, such attack often progresses vertically downward due to gravity. The addition of 2–3% molybdenum in Type 316 stainless steel imparts some resistance, but

**Figure 18** Crevice corrosion of Type 304 stainless steel under barnacles in natural seawater.

**Table 7** Depth of localized corrosion attack on various stainless steels in natural seawater intertidal and immersion zones after 16 years' exposure

Alloy	Exposure zone	Ave of 20 deepest pits 1 year	Ave of 20 deepest pits 8 years	Ave of 20 deepest pits 16 years	Deepest pit over 16 years
410 SS	Tidal	1.17	1.70	2.72	P*
	Immersion	1.55	4.08	5.38	P
302 SS	Tidal	0.15	1.47	1.27	2.79
	Immersion	1.78	3.56	3.84	P
321 SS	Tidal	0.18	1.42	1.40	2.36
	Immersion	1.63	4.90	6.02	P
316 SS	Tidal	0.13	0.41	0.33	0.91
	Immersion	1.14	3.96	2.41	P

P – Perforation (of 6-mm plate).

not immunity to pitting in seawater compared to Type 304. Sufficiently high flow rates that prevent macrofouling attachments would be expected to mitigate pit initiation. However, even in the absence of macrofouling, attack can initiate if the inclusion (e.g., MnS) concentration is high. For example, rampant pitting is encountered in Type 303 'free machining' stainless steels because they contain sulfur or selenium alloying additions, which produce copious electrochemically active inclusions in the microstructure.

Localized corrosion experienced with Type 304 stainless steel often leads to selection and specification of Type 316 stainless steel in many seawater applications. This is unfortunate despite a wealth of available information in the published literature. Virtually all 300-series stainless steels are susceptible to crevice corrosion in seawater. It is not widely appreciated that Type 316 stainless steel is just as susceptible to this form of localized corrosion as Type 304 in typical seawater applications containing crevices, for example, at flange faces, under gaskets, under O-rings, under washers, at threaded connections, under lap joints, and so on. Crevice corrosion can also occur under disbonded paint films, under biofouling, under silt, and so forth. There is another mistaken, but again, unfortunately, widely held view that low carbon 'L' grades of 300-series stainless steels are somehow more resistant to pitting and crevice corrosion in seawater. This is simply not the case. The 'L' grades are beneficial for mitigating intergranular attack, which would otherwise occur at sensitized areas of the microstructure, for example, heat-affected zones associated with welds. **Figure 19** shows typical crevice corrosion of a Type 316L stainless steel pump shaft bearing sleeve in seawater service. Thus, if crevices are present, and some form of corrosion-control,

**Figure 19** Crevice corrosion of Type 316L stainless steel pump shaft sleeve in natural seawater.

for example, cathodic protection, is not applied, Type 316 stainless steel will crevice corrode in most aerated seawater applications. This fact is used in crevice corrosion testing in seawater where Type 316 specimens are routinely used as susceptible controls. In other words, the test is invalid if the Type 316 stainless steel controls do not crevice corrode.

Crevice corrosion of stainless steels in seawater has been investigated extensively over the past 30 years. The importance of DO transport to the stainless steel surface to maintain passivity is widely accepted. For example, the following minimum velocity relationship was derived from one laboratory study<sup>70</sup> on smooth-wall, Type 316 stainless steel tubes to prevent fouling in seawater:

$$v = 2.74 + 0.56 \log d$$

where  $v$  is the velocity ( $\text{m s}^{-1}$ ) and  $d$  is the tube inside diameter (m).

Another rule-of-thumb  $\sim 2 \text{ m s}^{-1}$  minimum seawater velocity is commonly recommended to prevent settlement of silt and macrofouling under which localized attack can initiate and propagate. This type of approach is fraught with problems in practice because it is virtually impossible to maintain flow without interruptions. Experience indicates that macrofouling which attaches during extended stoppages is not usually removed when flow is resumed. Furthermore, it is very difficult to eliminate 'man-made' crevices completely in most components and seawater applications. The seawater electrolyte in the crevice is stationary even if high flow conditions exist outside the crevice. Thus, if a material is susceptible to crevice corrosion, maintaining sufficient flow to prevent fouling (outside the crevice) will not prevent attack within the crevice, as also discussed earlier.

The data in **Table 8** show that the maximum depth of crevice attack in seawater for three stainless steel alloys at 28 °C seawater temperature is greater than at 12 °C, but decreases markedly at 50 °C.<sup>71</sup> As discussed earlier, this behavior is often attributed to enhanced biofilm activity in warm seawater compared to cold or hot seawater.

As stated earlier, Cr and Mo are the primary alloying elements that influence localized corrosion resistance of stainless steels in seawater. Service experience<sup>72</sup> and tests<sup>73</sup> have shown that significant crevice corrosion resistance in ambient temperature seawater is attained with austenitic stainless steels of the nominal composition 20Cr–25–Ni–6Mo. However, even these 6Mo alloys have been shown to be prone to crevice attack if the seawater temperature exceeds their critical crevice corrosion temperatures (CCT), typically in the 30–45 °C range depending on the exact composition. Crevice attack on these alloys has also been demonstrated in tests conducted on painted panels even with relatively small areas left uncoated.<sup>74</sup>

**Table 8** Maximum depth of crevice attack in natural seawater in 30-day test at three temperatures

Alloy	Maximum depth of crevice attack (mm)		
	12 °C	28 °C	50 °C
304 SS	0.56	0.81	0.12
316 SS	0.34	0.57	0.05
Alloy 20	0.18	0.20	0

Duplex stainless steels are also potentially susceptible to crevice corrosion depending on alloy composition, crevice geometry, and service or test conditions. The higher Cr-containing alloy 2507 is generally more resistant to crevice corrosion than the lower Cr alloy 2205. Successful use of higher Cr duplex stainless steel has been reported in offshore and desalination seawater pumps, valves, and piping systems<sup>75</sup> normally at temperatures below their CCT ( $\sim 40^\circ\text{C}$ ) and chlorine levels of 0.5 ppm or less.

Critical crevice corrosion temperatures of stainless steels are usually determined using the ASTM G 48 standard test.<sup>76</sup> Test conditions are accelerated by using an aggressive test solution consisting of 6%  $\text{FeCl}_3 + 1\%$  HCl. Test specimens are fitted with PTFE multiple crevice assembly (MCA) washers torqued to 0.28 N m and exposed to the test solution at various thermostatically controlled temperatures. The CCT of the test alloy is the temperature at which crevice attack  $\geq 0.025 \text{ mm}$  is detected after 72 h immersion. Critical pitting temperatures (CPT) also commonly reported in the literature refer to pitting corrosion observed in the absence of artificial crevices; any edge attack on the test specimens is discounted. For any given alloy, the CPT is always greater than the CCT. However, the latter is generally considered more meaningful for practical applications because it takes into account the unavoidable crevices that are either man-made (e.g., gaskets, O-rings, sleeves) or naturally occurring (e.g., barnacles, thermal scale, silt).

In addition to CCT, stainless steels are also frequently ranked for likely crevice corrosion behavior in seawater based on their pitting resistance number (PREN). The following is a typical empirical expression for PREN based on alloy (wt%) composition:

$$\text{PREN} = \% \text{Cr} + 3.3\% \text{Mo} + A\% \text{N}$$

where the value of  $A$  is typically chosen to be 30 for austenitic stainless steels, and 16 for duplex stainless steels. **Table 9** shows the PREN and CCT values for a number of stainless steels.<sup>77</sup> It is apparent that as the PREN increases, the CCT increases. The following expression was proposed<sup>78</sup> for austenitic stainless steels:

$$\text{CCT} = (2.7 \times \text{PREN}) - 0.81$$

At first sight, this appears to be a very convenient method for ranking alloy performance in terms of expected localized corrosion resistance. However, for reliable materials selection, neither the PREN nor the CCT (as determined by the ASTM G 48

**Table 9** Typical PRE numbers versus CCT and CPT values for various stainless steels

Alloy	UNS No.	PRE	CCT (°C)
316L	S31603	26	<5
317L	S31783	28	0
2205	S31803	34	17.5–25

test method) provides a consistently accurate prediction of actual crevice corrosion resistance in seawater service. In other words, even alloys with high PREN and CCT values have been shown to crevice corrode, for example, in tests with severe crevice geometries.<sup>74</sup>

In crevice corrosion testing in seawater, crevice geometries can be created in a number of ways. For example, for flat sheet or plate stock, nonmetal or metal crevice-forming washers are commonly used as bolted assemblies; rubber O-rings and vinyl sleeves are used for tubular and round bar, and so on. Some of these devices and methods are described in ASTM standard G 78.<sup>79</sup> For irregular-shaped components or surfaces, for example, protruding weld beads, that do not readily permit the use of conventional crevice-formers, the use of paint coatings as crevice-formers has been proposed.<sup>80</sup> This methodology is based on the observation of crevice attack under coatings (e.g., marking inks, paint overspray, disbonded coatings, etc. on stainless steel surfaces) in actual practical applications.

Surface finish can also affect crevice corrosion resistance of stainless steels. The generally greater resistance of rough-ground surfaces to crevice attack, compared to smooth polished ones, is explained in terms of crevice tightness with respect to the crevice former. A certain degree of surface grinding and/or pickling is considered essential to remove the surface layer that is considered to have suffered some Cr depletion during manufacturing and/or fabrication (e.g., hot rolling, annealing, welding, etc.). The surface treatment is also intended to remove any extraneous particles (e.g., embedded iron) from tools, which can impair corrosion resistance; removal of embedded iron by immersion in acid solution (e.g., HNO<sub>3</sub>) is often erroneously referred to as 'passivation.' Chromium

carbide (Cr<sub>23</sub>C<sub>7</sub>) precipitation occurs at grain boundaries, typically in the 500–800 °C temperature range during welding and heat treatment of austenitic stainless steels. Corrosion resistance of areas adjacent to the carbide particles is lowered because of Cr depletion. However, despite this, no significant incidences of intergranular corrosion in ambient temperature seawater have been reported. On the other hand, precipitation of sigma phase (FeCr intermetallic), which can form in the temperature range 565–925 °C in Mo-containing austenitic steels, is considered more deleterious for seawater corrosion resistance.<sup>81</sup> Although their compositions are not exactly the same, cast stainless steels often exhibit lower resistance to localized corrosion than the corresponding wrought material. In the case of austenitic stainless steels, this is generally due to the residual ferrite phase in castings (necessary to counteract shrinkage during solidification). Welds represent 'miniature' castings, and hence their corrosion resistance can be lower than the parent material of similar nominal composition. Laboratory tests have shown that pickling of welds increased the critical pitting temperature of a 25-Cr duplex stainless steel by ~20 °C<sup>82</sup>; presumably, the reason for this is elimination of heat tint and surface Cr depletion. A 'soft' start up has been recommended in situations where pickling is not possible in piping systems; apparently the procedure consists of initial exposure to cold seawater for at least 2 days, followed by exposure to cold chlorinated seawater for at least 5 days, before turning on the heat exchangers.<sup>75</sup> This method may not be very practical in geographical areas where cold seawater is not readily available.

As stated earlier, the type of crevice geometry and its dimensions can play a critical role in the determining crevice corrosion resistance of stainless steels. Generally, crevice corrosion severity increases with decreasing crevice gap (tightness) and increasing crevice depth. This has been demonstrated by mathematical modeling<sup>83</sup> and by experimental evaluations.<sup>84,85</sup> The critical values of pH and chloride concentration of crevice solutions to initiate crevice attack have also been determined<sup>83</sup>; results for four different stainless steels are depicted in Table 10. In crevice corrosion testing, ideally, the actual crevice geometry (gap and depth) and crevice-formers (gaskets, washers, O-rings, etc.) intended for the service environment should be used. Lack of proper simulation could result in incorrect indication of corrosion behavior in service, for example, insufficiently tight and deep crevices could lead to a false prediction of corrosion resistance and vice versa.

**Table 10** Critical crevice corrosion solution values

Alloy	$[Cl^-] (M)$	pH

Source: Oldfield, J. W.; Sutton, W. H. *Br. Corros. J.* **1980**, 15(1), 31–34.

Polluted seawater containing sulfides have not adversely affected the performance of stainless steels in seawater,<sup>86,87</sup> both at moderate ( $2.4 \text{ m s}^{-1}$ ) as well as high velocities<sup>88</sup> (up to  $50 \text{ m s}^{-1}$ ). This observed corrosion resistance is based on the results of testing and experience in seawater, which either already contained sulfide or to which sulfide was deliberately added. Lean stainless steel grades can however, be subjected to microbially influenced corrosion (e.g., especially at welds) where the sulfide is generated biogenically as a byproduct, especially under quiescent conditions.

In the absence of solid particulate matter (e.g., entrained sand), stainless steels can generally tolerate seawater velocities in the order of  $40 \text{ m s}^{-1}$  without any erosion–corrosion problems.<sup>88</sup> However, in service application such as pumps and valves, proper hydraulic design and operation are essential to preclude cavitation problems. Stainless steels are not immune to cavitation, but typically exhibit greater resistance than ‘softer’ materials such as carbon steels, copper-base alloys, and aluminum-based alloys.

In the passive condition, stainless steels are galvanically compatible with each other in seawater despite their somewhat different positions in the galvanic series. In the passive condition, stainless steels are not usually adversely affected by galvanic corrosion when coupled to more noble materials, for example, titanium, gold, graphite, etc. As stated earlier, when localized corrosion of stainless steel is observed at areas in intimate contact with such noble materials, there is a common tendency to attribute attack on the stainless steel to galvanic corrosion. Tests conducted with inert gasket materials, such as PTFE and graphite-impregnated gaskets have shown that attack on 300-series stainless steel flanges is just as severe as, or more so, with the PTFE gaskets compared to graphite-containing ones.<sup>44</sup> The attack on the stainless steel can be explained as crevice corrosion with both types of gasket. Conversely, it can be argued that if it was galvanic corrosion,

graphite should produce attack on even those stainless steels that exhibit resistance to crevice attack with PTFE gaskets. It has been shown that high alloy stainless steels are adversely affected when coupled to graphite in chlorinated but not natural seawater.<sup>89</sup> But this is also the case when stainless steels with nonabsorbent inert gasket materials are subjected to chlorine levels  $>2 \text{ ppm}$ .<sup>90</sup> It has been reported that crevice corrosion associated with synthetic fiber gasket materials which absorb water is less severe because of dilution of the crevice electrolyte.<sup>91</sup> This phenomenon has been used to advantage in the design of an electrochemical corrosion cell where crevice corrosion of a flat-stock test specimen is eliminated by flooding the specimen sealing gasket with distilled water.<sup>92</sup>

Crevice corrosion has been investigated electrochemically in a number of ways.<sup>80</sup> For example, in a remote crevice assembly, crevice formers are used to sandwich a small specimen (anode) which is then coupled to a separate, larger cathode specimen made of the same alloy as the anode. In an alternative compartmentalized cell design, the anode and cathode are exposed to two different solutions (anode – acidic, deaerated, high  $Cl^-$  solution; cathode – neutral, aerated solution), respectively. In both these designs, the crevice corrosion current associated with the couple is usually measured using a zero-resistance ammeter (ZRA). Although, the anode and cathode members are made from single pieces of the test alloy to eliminate unwanted crevices and immersed connections, unfortunately localized attack is sometimes observed on one or both electrodes at the waterline. Such attack is usually associated with salting out due to evaporation of the test solutions.

Comparisons have been made between pitting corrosion of stainless steels and crevice attack. This stems from the similarity observed between chemistry (low pH, high  $Cl^-$ ) of the electrolyte trapped in a pit and in a crevice. Pits can be regarded as microcrevices (e.g., initiating at sulfide, inclusions) associated with the microstructure, extraneous embedded particles (e.g., iron), under heat tints, ‘peaks’ folded over by mechanical processes such as coarse machining, grinding, and so on. **Table 11** shows that pitting corrosion of Type 316 stainless steel is reduced by more than an order of magnitude in ‘deaerated’ seawater at  $105^\circ\text{C}$ , but not eliminated because  $25 \text{ ppb } O_2$  is probably sufficient to initiate and sustain some attack. The degree of localized corrosion attack on susceptible stainless steels shows a decreasing trend with exposure depth in the ocean

**Table 11** Maximum pit depths on stainless steel in natural and deaerated seawater<sup>93</sup>

<i>Alloy</i>	<i>Seawater conditions</i>	<i>Exposure (days)</i>	<i>Max. pit depth (mm)</i>
316 SS	Aerated, natural, ambient temperature	486	2.4
316 SS	Deaerated, 105 °C, 25 ppb DO	547	0.12
304 SS	Deaerated, 105 °C, 25 ppb DO	547	0.60

as the dissolved O<sub>2</sub> content decreases in the deeper water; however, this trend is general but not necessarily always one-to-one, indicating that other factors are probably implicated in the corrosion process.

In ambient temperature seawater, nonsensitized austenitic and ferritic stainless steels are considered resistant to stress corrosion cracking (SCC). SCC of Type 316 stainless steel was reported in the vapor zone above boiling seawater, but not on fully immersed specimens.<sup>81</sup> Since oxygen is usually essential for SCC, the likely explanation is that boiling eliminated dissolved O<sub>2</sub> from the seawater. Other data indicated that SCC of Type 316 stainless steel in hot seawater (126 °C) containing 600 ppb O<sub>2</sub> was mitigated when the O<sub>2</sub> level was reduced to 30 ppb.<sup>93</sup>

Martensitic and precipitation-hardening (PH) stainless steels are more prone to SCC. In deep-ocean water tests,<sup>94</sup> SCC of 15–7PH in the RH950 and RH1150 condition, and 17–7PH in the RH1050 condition, was reported. No correlation between SCC susceptibility and tensile strength was observed. These failures occurred at low O<sub>2</sub> levels, leading to the inference that hydrogen embrittlement may be the operative mechanism, for example, due to acidity generation associated with localized corrosion. Extrapolation of results of accelerated SCC tests in boiling NaCl and MgCl<sub>2</sub> solutions (e.g., per ASTM standard G 38) to seawater applications should be done very cautiously. Although temperatures >50 °C are often cited as necessary for SCC of stainless steels, experience indicates that failures can occur even at ambient temperatures where localized corrosion (e.g., crevice attack) generates low-pH conditions; of course, the material has to be in a susceptible condition, for example, sensitized, containing martensite, or containing high tensile stresses, and so on. Dynamic tests such as slow strain rate and crack growth rate are now strongly favored over static tests which may otherwise falsely indicate resistance, because the former expose the base metal

by almost constantly deforming and cracking the passive film above certain strain rates. Another major attribute of the dynamic SCC tests is the much shorter testing time compared to the static tests.

The greater SCC resistance of cast stainless steels over wrought material is usually ascribed to residual ferrite phase in the former. Polluted or putrid seawater containing sulfides may increase the susceptibility to hydrogen embrittlement of martensitic and PH and stainless steels; this propensity is increased when the material is deliberately or inadvertently under cathodic protection. Duplex stainless steels may also be susceptible under the latter condition. If SCC propensity decreases above a certain threshold temperature, especially in sulfide environments, it is reasonable to infer that the cracking mechanism is hydrogen embrittlement since outward diffusion of atomic hydrogen is temperature dependent. On the other hand, cathodic polarization increases the susceptibility to hydrogen embrittlement.

SCC failure of Type 316 stainless steel in venting systems of MSF desalination plants has been attributed to bromine.<sup>95</sup> Chlorination of seawater for biofouling control converts the bromide ions present in the seawater to bromine, which dissolves to produce hypobromous and bromic acids. If ammonia is present, bromoamines are also produced. Acidification of the seawater downstream for scale control releases hydrogen bromide into the vapor, which can then attack the susceptible stainless steels such as Type 316 in the venting system:

Cavitation susceptibility and ranking are often performed in laboratory tests in which the test specimen is vibrated ultrasonically in seawater by a magnetostrictive transducer. Cavitation resistance is based on mass loss per unit time and visual examination. Results for a number of alloys are discussed in the literature.<sup>96–98</sup> Such laboratory tests have shown decreased cavitation damage due to cathodic protection.<sup>97</sup>

## 2.18.7 Copper Alloys

Copper alloys rely on the formation of protective corrosion product films for corrosion control in marine environments. These films are sometimes described as ‘passive.’ In the author’s opinion, the term ‘passive film’ should be reserved for situations

(materials and conditions) where the film is very thin (typically <100 nm), optically transparent, extremely adherent, ennobles the potential of the metal appreciably, and not formed as a 'voluminous' deposit by the incorporation of species from the environment. For example, films on stainless steel, titanium, and aluminum would be considered as passive. The protective corrosion product films on copper alloys are much thicker and also quite complex; in clean seawater, copper hydroxychloride is often a major component.

In the splash and intertidal zones, 90/10 copper–nickel sheathing has been successfully used for corrosion control on offshore platforms. Unlike paint coatings, such sheathing requires little maintenance – which is extremely difficult in the splash zone as discussed earlier. Because of high resistance to macrofouling, copper–nickel has also been used for the construction of small boat hulls and as adhesive-backed foils on ferries and fireboats.<sup>99</sup> Macrofouling resistance is apparently reduced when the copper–nickel is galvanically coupled to a more anodic material such as steel, or if it is subjected to cathodic protection, *albeit* inadvertently. However, the macrofouling attachments are relatively easily removed compared to bare or coated steel.

Copper alloys are very desirable for seawater applications because of high resistance to biofouling. They have been widely used for heat exchanger tubing because of high heat transfer properties. However, they are relatively soft and hence subject to erosion–corrosion in seawater above certain velocities. The high turbulence in seawater pumps restricts the choice of copper alloys largely to nickel–aluminum–bronze. As a general rule of thumb critical velocities for small diameter heat exchanger tubing determined from laboratory testing and field experience are shown in [Table 12](#).<sup>100</sup> These values are still widely used in design and operation of copper-alloy heat exchangers. It has been postulated that each copper-based alloy has a critical shear stress associated with it.<sup>101</sup> When this shear stress exceeds the adhesion strength of the protective corrosion product film, attack of the base metal ensues. Critical shear stresses, depicted in [Table 13](#),<sup>101</sup> determined using fluid mechanics and evaluated by laboratory testing now support the view that as the piping diameter increases, higher critical velocities than those shown in [Table 12](#) can be used without increasing the risk of erosion–corrosion for the alloy in question.

One of the most important corrodents toward copper alloys in seawater service is sulfide. Sulfide can be entrained in the seawater (e.g., from bottom

sediment or polluted harbors) or generated *in situ* by sulfate-reducing bacteria, as discussed previously. The latter mechanism is very common when initially clean seawater putrefies after a few days of stagnation, for example, in heat exchangers, pumps, and piping systems during outages or shutdowns. The role of sulfides has been extensively investigated.<sup>102–108</sup> The evidence suggests that protective corrosion product films allowed to form on copper alloys in clean seawater for several months can resist short subsequent exposure to sulfides. Conversely, exposure to sulfide conditions from the outset interferes with the formation of desirable protective films. In such cases, sulfides have a deleterious effect on pitting corrosion and erosion–corrosion resistance. Thus, commissioning of copper alloy equipment such as heat exchangers using clean seawater for several months initially appears to be critical. However, this task should not be underestimated as access to large quantities of clean seawater at coastal areas is difficult

at best. Experience indicates that once incorporated in the corrosion product film, sulfides are very difficult to remove completely and problems continue.

A classical laboratory study<sup>102</sup> of the effects of sulfide on 90/10 and 70/30 CuNi in seawater disclosed the following: corrosion rate increased as the sulfide content was increased from 7 to 250 ppb; attack was localized at lower sulfide concentrations, and more general at higher ones; once attack initiated, there was minimal seawater velocity effect over the 0.5–5.3 m s<sup>-1</sup> range; attack continued even in clean seawater after initial exposure to 1000 ppb sulfide for 1–5 days, or 10 ppb sulfide for 30 days. Addition of 0.2 ppm ferrous ions which is sometimes used to mitigate erosion–corrosion was found to reduce but not eliminate sulfide-related corrosion of the CuNi alloys.<sup>103</sup>

Protective corrosion product films reduce the corrosion rate markedly in clean seawater with time.<sup>109</sup> In the ambient temperature range, the corrosion rate increases with increasing temperature. However, at high temperatures, such as in MSF desalination plants, the corrosion rate decreases with increasing temperature<sup>110</sup> in the 54–121 °C temperature range as illustrated in **Figure 20**. This may be due to the lower oxygen levels and precipitation of scales due to inverse solubility. However, at elevated temperature, corrosion rate increases with increasing dissolved O<sub>2</sub> even in the ppb range as depicted in **Figure 21**.<sup>111</sup> Decrease in corrosion rate has also been reported for deep waters where oxygen levels were lower.<sup>112</sup>

It should be emphasized that copper alloys with >70% copper are resistant to biofouling compared, for example, to carbon steel, stainless steels, aluminum, titanium, but not completely immune. Macrofouling resistance of copper alloys is usually explained in terms of either continuous, but slow release of copper ions, or presence of copper-rich corrosion products on the metal surface – both of which are purportedly ‘toxic’ toward macroorganisms.<sup>113,114</sup> The situation is confounded by the fact that while increasing alloy content lowers the copper ion release (and hence likelihood of fouling), it also affects the nature of corrosion products. It is not known why, for instance, barnacles attach at some but not most areas of such copper alloys. It has been suggested that attack on the metal under macrofouling occurs after the organisms die.<sup>113</sup> Fouling is more likely in quiescent than flowing seawater. A minimum velocity of 1–2 m s<sup>-1</sup> was proposed to mitigate macrofouling.<sup>115</sup> Higher velocities to prevent macrofouling may increase the risk of erosion–corrosion.

Pitting corrosion of copper alloys can occur under deposits due to differential aeration, and is often exacerbated by sulfides. Another factor that can increase pitting susceptibility is the presence of residual carbon films on the copper surface.<sup>116</sup> The carbon is believed to derive from oxidation of lubricating oil residues left behind from manufacturing (e.g., tube drawing) and subsequent annealing heat treatment. It has been hypothesized that the carbon film acts as a cathode and promotes localized corrosion of the base metal at exposed areas in the film. Ideally, the carbon film should be removed after

**Figure 20** Corrosion rate versus temperature for three copper-base alloys in seawater; DO 40–600 ppb, pH 6.2–7.8, 156 days. Reproduced from Mattson, M. E.; Fuller, R. M. A study of materials of construction in distillation plants, Joint report by Office of Saline Water and the International Nickel Company, Research report No. 163, 1965.

**Figure 21** Corrosion rate versus DO in seawater for three copper-base alloys at 107 °C in a once-through desalination system; seawater flow rate  $\sim 2 \text{ m s}^{-1}$ , pH 7.2–7.5,  $\text{CO}_2 < 10 \text{ ppm}$ , 15–30 days. manufacturing. Detection of the carbon film is not always easy. Since the carbon film is insoluble, one method involves placing a drop of nitric acid on the test surface and visually observing any flakes of thin gray/black matter float up to the top. The films are often even more difficult to detect after corrosion failures have occurred. Potential measurement has been proposed as a detection method in such cases.<sup>117</sup>

A number of copper-based alloys tested concurrently in an ancillary seawater condenser operated for over 8 months revealed that Admiralty brass (70/30 Cu/Zn) suffered from impingement corrosion at the inlet and outlet ends as well as adjacent to deposits.<sup>118</sup> Iron and manganese additions to copper–nickel alloys have been shown to enhance erosion–corrosion resistance.<sup>119</sup> However, some other tests indicated iron additions to be deleterious,<sup>120</sup> especially  $>1\%$ .<sup>121</sup> This was probably related to the distribution of iron in the microstructure. Uniform distribution improves corrosion resistance, while segregation increases susceptibility to localized attack. A simple magnetic permeability test is used to detect iron segregation.<sup>122</sup> Small Cr additions to copper–nickel alloys improves erosion–corrosion resistance; however, localized corrosion resistance in quiescent conditions may be impaired by Cr segregation. Any restrictions on flow caused by macrofouling (e.g., shells) or pebbles lodged in the tube can cause severe local turbulence, and hence erosion–corrosion or impingement attack at associated (usually immediately downstream) areas. Experience shows that less protective scales are formed as the seawater pH is

lowered, for example, by pollutants or dissolved  $\text{CO}_2$ . This is not unexpected since corrosion products and mineral scales are more difficult to form at lower pH values. Absence of protective scales at lower pH will increase erosion–corrosion tendency.

The role of gas bubbles in promoting erosion–corrosion has been discussed.<sup>121,123</sup> In rotating spindle and disc tests, air bubbles in the seawater were stated to be beneficial toward CuNi alloys.<sup>121,124</sup> However, results of impingement attack in flowing loop tests indicated that both air and nitrogen bubbles were harmful.<sup>121</sup> Since collapsing bubbles are thought to be the cause of cavitation damage, copper alloys, being considerably softer are more likely to be affected by this form of damage compared to, say, stainless steels, nickel-based alloys, and titanium.

Investigations on the effect of entrained sand particles on erosion–corrosion resistance of aluminum brass indicated the following: erosion–corrosion increased with increasing sand content ( $>300 \text{ ppm}$ ) and particle size<sup>125</sup>; cathodic protection with or without ferrous iron injection was beneficial when the sand particles were  $50 \mu\text{m}$  in size, but not when they were  $250 \mu\text{m}$ <sup>126</sup>; less attack in polluted seawater containing sand was attributed to protective sulfide films.

Galvanic corrosion of copper alloys is problematic in seawater when they are coupled to cathodic materials such as stainless steels, nickel-based alloys, titanium, and graphite, especially for small anode/cathode area ratios. In chlorinated seawater, a reduction in galvanic corrosion of copper alloys coupled to stainless steels has been observed<sup>43,128</sup> and ascribed to reduced biofilm

activity, which affects cathodic polarization kinetics, and hence galvanic corrosion rate.

Copper alloys are cathodic to many materials, and can thus cause unacceptable galvanic corrosion of anodic materials such as carbon steel, cast iron, aluminum, and zinc – particularly for large cathode/anode area ratios. Gray cast irons are initially anodic to copper; however, graphitic corrosion of gray cast iron can eventually expose enough graphite at the exposed surface so as to reverse the galvanic couple and accelerate corrosion of the copper alloy. In principle, the free corrosion potentials of copper-based alloys in seawater are fairly close to one another, and thus one might expect them to be galvanically quite compatible. In principle, this is the case. However, regardless of potentials, an adverse cathode/anode area ratio between two copper alloys can produce unacceptable galvanic attack on the more anodic material. Increasing flow rate and temperature typically accelerates galvanic corrosion of copper alloys. Presence of sulfides (especially 50 ppb) in seawater was found to promote galvanic attack on Naval M-bronze and nickel aluminum bronze fittings coupled to 90/10 or 70/30 CuNi piping.<sup>128</sup> The effect of sulfides appears to be greater at lower seawater temperatures.<sup>129</sup>

Electrically isolated copper components in a system can undergo self-corrosion in seawater environments. The release of even imperceptible amounts of copper ions can pose an indirect problem for anodic materials that come in contact with them. For instance, copper ions can plate out on aluminum, steel, and zinc, leading to deposition or cementation corrosion. In other words, copper ions plate out on the anodic material (as a cathodic reaction) and cause corrosion of the base metal. However, once the ions have plated out, galvanic corrosion (usually as pitting) of the base metal ensues even if the original source of the copper ions is removed. Copper-colored areas surrounding pits in the anodic material are usually a telltale sign of this phenomenon. For example, it has been observed in aluminum fuel tanks on pleasure boats, particularly those operating in seawater environments. Copper corrosion products enter the tank from water condensate in copper piping and/or copper alloy valves in the fuel system.

Copper-based alloys are quite resistant to SCC in clean seawater. SCC of brasses is generally associated with ammonia, amines, or nitrates that are either entrained as pollutants or can form *in situ* under decaying biofouling attachments. Copper–nickel alloys are considered resistant to such environments. Stress relief

of cast nickel aluminum bronze alloys is recommended to minimize the risk of SCC failure in critical seawater service applications.

Dealloying is quite common in many copper-base alloys. It is often observed in marine artifacts submerged for long periods in seawater. Reddish coloration due to copper deposition is a telltale sign of dealloying. Alpha brasses (e.g., 85/15 Cu/Zn) can be inhibited against dealloying with Sn or As additions. Unfortunately, such additions are usually not considered to be as effective in beta brasses (e.g., 60/40 Cu/Zn). Unlike in brasses, dealloying in copper–nickels is usually superficial. In nickel aluminum bronzes, dealloying involves the selective dissolution of aluminum from the alloy. Proper heat treatment to minimize the beta phase alleviates this problem.

Copper-base alloys can suffer from another form of localized attack known as metal-ion concentration cell corrosion. Attack usually occurs at the mouth of a crevice, in contrast to localized corrosion that occurs inside the crevice, for example, in susceptible stainless steels and nickel-base alloys.

## 2.18.8 Nickel-Based Alloys

The primary nickel-based materials used in seawater include nickel–copper alloys (e.g., the 70/30 NiCu alloy 400, or its high strength version, alloy K-500) and Ni–Cr–Mo–Fe alloys (e.g., alloy 625, C-276, alloy 59, alloy 686, etc.). As with stainless steels, these nickel-based alloys are also believed to depend on the formation of passive films for corrosion resistance.

Because of its established record of good performance in the splash zone, alloy 400 has been successfully used as sheathing for protection of carbon steel in the splash zone.<sup>46</sup> Unlike the copper–nickel alloys described in the previous section, the NiCu and other nickel-based alloys are not resistant to macrofouling in the tidal and immersion zones. In fact, nickel-base alloys tend to behave more like stainless steels. General corrosion rates in clean seawater are low to negligible, and when attack occurs, it is usually as pitting and/or crevice corrosion; corrosion initiation is more likely in quiescent or low flow seawater.

For unalloyed nickel and nickel–copper alloys (e.g., alloys 400 and K-500), pitting in low flow seawater is common. Unlike with susceptible stainless steels, the pits tend to be open, hemispherical, and do not grow significantly in depth, for instance, after ~1 year in seawater.<sup>130</sup> Alloying nickel with copper appreciably improves the pitting resistance. Seawater

temperature has been shown to dramatically affect pitting corrosion behavior of alloy 400; maximum pit depth increased in the 18 to 30 °C range, but then decreased markedly at 50 °C.<sup>131</sup> A similar trend was discussed earlier for crevice corrosion of stainless steels and attributed to 'degraded' biofilms at 50 °C. The pitting potential of alloy 400 determined electrochemically decreased with temperature.

Corrosion rate of alloy 400 has been shown to increase as the sulfide concentration in seawater increased from 0 to 5 ppm.<sup>128</sup> Ni–Cr alloys were not affected by sulfides in ambient temperature seawater.

Alloying additions of ~20% Cr and ~8% Mo to nickel-based alloys (e.g., in alloy 625) impart significant resistance to pitting and crevice corrosion in seawater. As with stainless steels, addition of ~20% Cr alone does not ameliorate localized attack. **Table 14** provides a comparison of relative corrosion resistance of several nickel-based alloys immersed in quiescent seawater for ~18 months.<sup>132</sup> Apparently, from a corrosion resistance viewpoint, cobalt in Ni-based alloys behaves like nickel. Alloy C-276 was found to be highly-resistant to localized and general corrosion in seawater up to 288 °C<sup>71</sup>; it also exhibited crevice corrosion resistance at 107 °C in deaerated seawater (DO 28 ppb).

Crevice corrosion of alloy 400 is not generally as severe as, say, for 300-series stainless steels. This can be explained by the fact that hydrolysis of Ni and Cu ions from alloy 400 does not produce a highly acidic and aggressive crevice solution compared to Cr and Mo ions from susceptible stainless steels.

The erosion–corrosion behavior of nickel-based alloys is quite similar to that of stainless steels, that is, notably superior to that of copper–nickel alloys. Thus, nickel alloys can tolerate high velocities, turbulence, and impingement which makes them candidates for seawater pumps, valves, piping systems, and so on. Test data summarized in **Table 15**<sup>133,134</sup> show that, like stainless steels, most nickel-based alloys exhibit acceptably low erosion–corrosion rates up to ~40 m s<sup>-1</sup>. With the exception of the NiCu alloys, their cavitation resistance is also expected to be similar to that of stainless steels.

Nickel–copper alloys are often selected for seawater service because their higher Ni content provides enhanced resistance to chloride stress corrosion cracking (Cl<sup>-</sup> SCC) compared to stainless steels. Deep ocean tests of 2 years duration confirmed the SCC resistance of Alloy 825 and Alloy C.<sup>135</sup> Alloys G-3, 625, and C-276 were resistant to SCC in U-bend tests of several hundred hours duration in synthetic seawater.<sup>81</sup>

Because of their austenitic microstructure, nickel-based alloys are generally resistant to hydrogen embrittlement in the annealed condition. However, risk of hydrogen embrittlement (HE) increases as the strength level increases due to cold work or heat treatment. At similar strength levels, increasing aging temperature is apparently favorable in lowering HE risk. HE of 70/30 NiCu alloy K-500 bolts has been reported for an offshore platform application under cathodic protection conditions.<sup>136</sup> Susceptibility to HE was traced to high hardness and subsequent cathodic protection. Annealing after rolling the threads to alleviate high hardness before precipitation hardening was recommended to mitigate the problem.

Accelerated attack would be predicted for active materials coupled to Ni-based alloys because of the noble positions of the latter in the galvanic series. However, the successful use of alloy 400 sheathing on carbon steel in the splash and tidal zones, even in the

absence of cathodic protection, suggests galvanic compatibility which has been attributed to easy cathodic polarization of the nickel alloy.<sup>137</sup> It should be emphasized that this would not be the case if the steel/nickel-alloy area ratio was small. Pitting and crevice corrosion of NiCu alloy trim in pumps and valves is mitigated by cast iron bodies. Although nickel-based alloys are anodic to titanium, they are galvanically compatible because the increased corrosion rates are still very small from a practical viewpoint.<sup>138</sup>

### 2.18.9 Titanium Alloys

Titanium alloys are among the most corrosion resistant materials in seawater service. The general corrosion rate in seawater is extremely low, for example,  $0.8 \text{ nm year}^{-1}$ ,<sup>140</sup> not surprisingly, it is often reported as 'nil.' Titanium alloys are immune to pitting and crevice corrosion in all marine environments at ambient temperatures. Thus, no localized corrosion is encountered in the atmospheric, splash, tidal, immersion, or mud zones. Titanium is not resistant to biofouling. Therefore, macrofouling attachments similar to those on carbon steel, stainless steel, and aluminum alloys are also commonly observed on titanium alloys. However, unlike the other alloys, there is no localized corrosion of titanium under the biofouling or any silt deposits. No corrosion allowance is necessary for titanium because of its very high corrosion resistance in ambient-temperature seawater. Thus, titanium is widely used for heat exchanger applications, especially retubing in shell-and-tube heat exchangers. Grade-1 titanium is the premier material of choice for plate-and-frame heat exchangers because of high corrosion resistance and easy fabrication properties. However, because of extensive demand, there is currently a worldwide shortage of grade-1 titanium. Other materials such as Ni–Cr–Mo alloys and superaustenitic stainless steels are being evaluated as alternatives.

Crevice corrosion of titanium in seawater has been reported in tight crevices at temperatures  $>70^\circ\text{C}$ .<sup>141,142</sup> The crevice electrolyte was also found to be acidic, suggesting that a similar oxygen-depletion and metal-ion hydrolysis mechanism (as discussed earlier for stainless steels) may be operative. However, the actual mechanism is probably more complex since crevice corrosion resistance is increased by small additions of Pd, Mo, or Ni to the titanium. Iron, carbon steel or low-alloy steel particles embedded accidentally into a titanium surface can lead to

localized attack at temperatures  $>80^\circ\text{C}$ . This has been proposed as a special case of crevice corrosion,<sup>142</sup> that is, occlusion by titanium metal smears or laps may create micro crevices that allow the generation of acidic conditions, preventing repassivation and localized attack, and possibly hydrogen adsorption. Thus, the mechanism is probably more complex than the presence of just micro crevices, since the attack has not apparently been observed if austenitic stainless steel, nickel, or copper particles are embedded in the titanium surface. Evidently, the Pd-containing grades exhibit significant resistance to attack associated with smeared iron particles.

Titanium is quite noble in the galvanic series for seawater. It can sometimes exhibit potentials anodic to graphite, platinum, zirconium, Ni–Cr–Mo–Fe alloy C, and NiCu alloy 400, and even some 300-series stainless steels in the passive condition. However, titanium is galvanically compatible with these materials. Any attack on the titanium is more likely to be crevice corrosion in tight crevices at temperatures  $>70^\circ\text{C}$ , as discussed earlier. In fact, despite being slightly more noble than titanium, attack is much more likely on the 300-series stainless steels, alloy 400, and even alloy C, at crevices regardless of galvanic coupling to titanium. Corrosion of the more active materials such as copper-base alloys, carbon steels, cast irons, aluminum alloys, zinc, and magnesium will be accelerated if galvanically coupled to titanium. The degree of attack acceleration will depend on the relative anode/cathode area ratio, system geometry, and cathodic reduction reaction kinetics on the titanium, which are influenced by seawater temperature, velocity, fouling, and so on. **Figure 12** shows that in seawater, titanium is more easily polarized than copper due to its higher overvoltage for oxygen reduction. Consequently, galvanic attack on carbon steel coupled to titanium is less severe compared to corrosion of steel coupled to copper, in each case for the same anode/cathode area ratio. The potential difference between titanium and steel is nearly double that between steel and copper – affirming that potential difference is not reliable for predicting galvanic attack on the anodic material. The free corrosion potential of titanium in aerated and deaerated seawater is fairly steady in the  $\sim 20\text{--}135^\circ\text{C}$  temperature range. However, as temperature increases further, the potential shifts in the electronegative direction by  $\sim 500 \text{ mV}$  at  $\sim 200^\circ\text{C}$ . Potentials of other alloys also exhibit electronegative shifts.<sup>143</sup>

Unfortunately, titanium is susceptible to hydriding when its potential shifts more electronegative

than  $-0.7$  V (SCE) at elevated temperature.<sup>144</sup> This can happen when titanium is cathodically polarized by coupling to anodic materials such as steel, aluminum, or zinc, or by impressed current cathodic protection. In ambient temperature seawater applications, a potential shift to no more than  $-1$  V (SCE) has been suggested.<sup>144</sup> Hydrogen is generated by a two-step process: (1) discharge of  $H^+$  to atomic H by electron consumption, and (2) H recombination to generate molecular  $H_2$  gas bubbles. If excessive hydrogen is generated, there is an increasing uptake of atomic hydrogen, which diffuses into the titanium, reacts with the  $\alpha$  phase, and precipitates as brittle, acicular, titanium hydride ( $TiH_2$ ) needles at grain boundaries. Hydriding is exacerbated at temperatures  $>80^\circ\text{C}$ . About 500–600 ppm, hydrogen can cause excessive hydriding which embrittles the titanium, causing potentially significant reduction in ductility and fracture toughness. Anodizing reduces hydrogen uptake. The beta titanium alloys do not hydride easily because of considerably higher solubility of hydrogen (several 1000 ppm) in the beta phase.

It was prematurely concluded from early tests that unwelded titanium was highly resistant to stress corrosion cracking (SCC) in seawater<sup>145</sup> even when stressed to 75% of the yield strength. However, those tests used smooth test specimens. Subsequent tests disclosed that while alloy composition and heat treatment influenced SCC resistance, presence of notches simulating stress risers was essential. Environmental variables did not greatly affect the SCC behavior, this is not surprising because of the very high resistance of titanium to corrosion in seawater. Generally, all the  $\alpha$  alloys (e.g., Ti–8Al–1Mo–1V and Ti–7Al–3Nb–2Sn), and near  $\alpha$  alloys that contain small amounts of  $\beta$  phase stabilizers such as Al, Zr, Sn, and O (e.g., Ti–6Al–5Zr–0.5Mo–0.2Si and Ti–8Al–1V–1Mo) are susceptible to SCC in seawater. SCC resistance is markedly reduced when Al  $>5\%$  and oxygen  $>0.4\%$  in  $\alpha$  alloys. For the  $\alpha + \beta$  alloys, such as grade 5, oxygen concentration  $<0.1\%$  is necessary to preclude SCC; commercial alloys contain typically 0.15% oxygen. In  $\alpha + \beta$  alloys, cracking occurs primarily in the  $\alpha$  phase. Contradictory behavior has been indicated for the effect of  $\beta$  stabilizers on SCC resistance in seawater. In some cases, V and Nb additions were detrimental, in others,  $>2\%$  V was advantageous when Al in the 7–8% range was present in the alloy. In  $\alpha + \beta$  alloys, Si and Mn were apparently deleterious.<sup>146</sup>

The SCC resistance of titanium alloys in seawater is greatly affected by heat treatment. Generally, small

grain size is attained by aging just below the  $\beta$  transus (above the  $\beta$  transus,  $\alpha$  or  $\alpha + \beta$  phases transform to  $\beta$ ) which enhances SCC resistance. For the susceptible alloys, the SCC behavior is also highly influenced by stress concentration; for example, there is a significant decrease in fracture stress in seawater at a notch radius of 125  $\mu\text{m}$  compared to 250  $\mu\text{m}$ . In slow strain rate tests in simulated seawater, SCC behavior of a number of titanium alloys was found to be highly influenced by the strain rate<sup>147</sup>; typically, they were most susceptible at strain rates of  $\sim 7 \times 10^{-5} \text{ s}^{-1}$ . Other laboratory tests revealed that crack velocity decreased linearly with cathodic polarization of titanium alloys over the  $-400$  to  $-900$  mV (SCE) potential range<sup>148</sup>; the opposite behavior would be expected if there is sufficient uptake of hydrogen, for example, due to extended precharging time and/or polarization to more negative potentials in test. Crack velocity was found to increase with temperature, exhibiting Arrhenius behavior.<sup>149</sup> In tests performed in surface seawater and at depths of  $\sim 800$  and  $\sim 2000$  m, only butt-welded, nonstress relieved, Ti–13V–11Cr–3Al alloy stressed to 75% of yield strength exhibited SCC.<sup>150</sup>

The passive oxide film, its ability to reheal, and high inherent hardness of titanium confer high resistance to erosion–corrosion and cavitation in seawater. Velocities as high as  $\sim 37 \text{ m s}^{-1}$  can be tolerated in clean seawater. Minimum velocities of the order of  $>2 \text{ m s}^{-1}$  are necessary to prevent attachment of macrofouling in seawater heat exchanger tubing and piping. Provided they are galvanically compatible, titanium inserts can be used in the inlet ends of heat exchanger tubing experiencing erosion–corrosion at those locations. Ordinary silt in seawater does not lower erosion–corrosion appreciably. Higher-strength titanium alloys, such as grade 5 (Ti–6Al–4V), can be substituted for enhanced resistance if large, angular, abrasive particles produce erosion of the commercial purity (CP) grades.

The anodic breakdown potential of titanium in ambient temperature seawater is  $\sim 10$  V. This allows titanium to be used as a substrate for platinum in impressed current anodes. If higher breakdown voltages are necessary in specific applications, niobium is substituted for titanium.

## 2.18.10 Aluminum Alloys

The low density of aluminum alloys ( $\sim 2700 \text{ kg m}^{-3}$ ) makes them attractive for marine engineering

applications such as seacraft. However, the corrosion resistance is quite variable depending on alloy composition and heat treatment. **Table 16** summarizes a commonly used designation system for aluminum alloys. For some applications, 'Alclad' products are specified. Alclad refers to a composite wrought (e.g., sheet) material which has an aluminum-alloy core with a metallurgically bonded thin 'skin' of either pure aluminum or another aluminum alloy on its surface for corrosion protection, for example, high-purity (more corrosion resistant) aluminum over alloy 2024, or alloy 7072 applied over alloy 6061 as sacrificial coating.

Aluminum relies on the formation of a passive aluminum oxide ( $\text{Al}_2\text{O}_3$ ) film for corrosion resistance. However, the film properties are affected by alloy composition, metallurgical condition, and environmental factors, and widely ranging corrosion behavior is exhibited in seawater. In seawater immersion, the major corrosion concerns with aluminum alloys are galvanic corrosion when electrically coupled to cathodic materials, crevice corrosion and pitting under macrofouling and silt deposits, exfoliation, stress corrosion cracking, and metal-ion (especially Cu) deposition corrosion. The high strength 2xxx series and the 7xxx series aluminum alloys are widely used in aerospace applications. However, the alloying additions of Cu (in 2xxx) and Zn (in 7xxx) also make them more susceptible to corrosion in seawater.

Unalloyed aluminum has very low general corrosion rate in the splash zone because DO diffuses easily through the thin seawater layer to sustain passivity associated with the  $\text{Al}_2\text{O}_3$  film. However, pure aluminum is considered too 'soft' for many splash-zone applications. The stronger 5xxx and 6xxx alloys are more suitable. In the tidal zone, aluminum alloys

are subject to biofouling and localized attack (pitting and/or crevice corrosion) underneath macrofouling attachments. Long-term exposure tests<sup>133</sup> showed that the average penetration for alloys 1100 and 6061 in the tidal zone after 16 years exposure was very low,  $<15\text{ }\mu\text{m}$ ; however, the maximum pit depths were  $\sim 1\text{--}1.5\text{ mm}$ . Under immersion conditions, the average penetration increased but was still very low from a practical viewpoint,  $<30\text{ }\mu\text{m}$ ; however, maximum pit depths were in the range  $\sim 1\text{--}2\text{ mm}$ .

The effect of alloying additions is complex. For example, depending on specific alloy,  $<0.2\%$  Cu and  $\sim 0.5\text{--}1.2\%$  Mn were beneficial, but  $0.4\text{--}0.8\%$  Fe was detrimental toward corrosion resistance of aluminum in synthetic seawater.<sup>151</sup> Heat treatment affects the distribution and size of the intermetallic particles that influence mechanical properties by precipitation hardening. The desired mechanical properties of 5xxx alloys cannot be attained by conventional heat treatment alone; instead, they are strain hardened by mechanical working and, depending on alloy, may be subjected to some annealing treatment. The selected data in **Table 17** show that the general corrosion rate of alloy 5052 in the H22 temper was an order of magnitude lower than in the annealed 'O' condition; the H32 temper reduced the corrosion rates of alloys 5086 and 5456 by half, but the H113 temper did not significantly affect the corrosion rate of alloy 5085.<sup>152</sup>

**Table 16** Aluminum wrought alloy designations

Series	UNS No.	Major alloying element(s)	Heat treatable
1xxx	A91xxx	None	No
2xxx	A92xxx	Cu	Yes
3xxx	A93xxx	Mn	No
4xxx	A94xxx	Si	No
5xxx	A95xxx	Mg	No
6xxx	A96xxx	Mg, Si	Yes
7xxx	A97xxx	Zn, Mg	Yes
8xxx	A98xxx	Ti, Li	No
<i>Temper (heat treatment) designations</i>			
O	Annealed		
H (e.g., H1, H2, etc.)	Strain-hardened only		
T (e.g., T4, T6, etc.)	Solution heat treated; aged

The increase in corrosion rate of aluminum alloys with seawater depth is often attributed to lower oxygen content of seawater, which presumably prevents rehealing of the aluminum oxide film. Lower seawater pH (and hence less likelihood of calcareous deposit formation) in deep water has been proposed as an alternative explanation.<sup>153</sup> However, this rationalization appears to be contradicted by data<sup>154</sup> from artificial seawater tests indicating that corrosion rate of Al–3Mg alloy decreased with decreasing pH in the 6–9 range. The mechanism is probably much more complex since alloy composition appears to affect corrosion behavior even at the same seawater depth. For example, maximum depth of pitting was <50  $\mu\text{m}$  for alloys 5086-H34 and 5083-H113 exposed for 1 year at a depth of  $\sim 250$  m, whereas the maximum pit depths for alloys 2219-T81 and 6061-T6 at the same depth were almost 2 mm.

Tests on alloys 3004, Alclad 3004, Alclad 3003, and 5052 exhibited less mass loss, but more pitting in cold seawater ( $\sim 10^\circ\text{C}$ ); in warm seawater ( $\sim 27^\circ\text{C}$ ), overall mass loss was greater but corrosion was uniform with no discernible pitting.<sup>155</sup> It was shown electrochemically that the pitting potential was not significantly altered by temperature,<sup>153</sup> however, ennoblement of the free corrosion potential indicated greater propensity to pitting in colder seawater. Data for Al–3Mg alloy indicate that corrosion rate increased steadily with temperature in the  $\sim 20$  to  $\sim 70^\circ\text{C}$  range, it then decreased somewhat with a minimum at  $\sim 90^\circ\text{C}$ , and finally increased rapidly above boiling to  $\sim 125^\circ\text{C}$ .<sup>154</sup> Increased corrosion at the lower temperatures was attributed to DO. A significant decrease in pitting corrosion of alloy 5052 was reported for hot, flowing seawater environment associated with desalination when the temperature increased from 82 to  $108^\circ\text{C}$ .<sup>156</sup>

Alloy composition and heat treatment appear to affect pitting corrosion behavior as illustrated by the data in Table 18 which show maximum depths of

**Table 18** Maximum depths of attack on some aluminum alloy plate specimens after 10 years immersion in natural seawater at ambient temperature

Alloy	Maximum pit depth (mm)
1100-H14	1.02
3003-H14	0.53
6061-T4	0.36
6061-T6	2.41
7072	1.42 (perforated)
7075-T6	1.68

attack on selected aluminum alloy plate specimens after 10 years exposure in seawater. Electrochemical studies have indicated that alloying additions of Zn lower the pitting potential of aluminum; Cu additions raise it, while Mg additions exhibit a minor effect. However, heat treatment to attain maximum hardness lowered the pitting potential of Al–Cu alloys; this is probably related to grain boundary depletion of Cu associated with precipitation of  $\text{CuAl}_2$  intermetallics particles at grain boundaries. Figure 22 shows an interesting relationship between pitting propensity and free corrosion potential for a number of aluminum alloys.<sup>175</sup> There is no general agreement on the growth rate of pits with time. Some data suggest that pit depth decreases with time; other data imply opposite behavior. Despite wide variations in pitting corrosion behavior, aluminum alloys are highly susceptible to crevice corrosion, and therefore require protection, especially when tight crevices are present. It is not known with certainty whether the crevice corrosion mechanism in aluminum alloys is similar to that in stainless steels because it has not been studied as extensively.

Aluminum alloys have been reported to be generally resistant to seawater up to velocities of  $\sim 6 \text{ m s}^{-1}$ .<sup>157,158</sup> However, critical velocities vary with alloy composition, heat treatment, and exposure time<sup>159,160</sup>; and attack morphology can change from pitting to increased general metal loss as velocity increases. Aluminum alloys being relatively soft are more susceptible to cavitation damage under turbulent flow conditions than, for example, stainless steels, nickel-based alloys, and titanium alloys. This means

**Figure 22** Depth of pitting on Al alloys versus free corrosion potential in seawater. Reproduced from Schumacher, M., Ed. *Seawater Corrosion Handbook*; Noyes Data Corporation: NJ, USA, 1979; p 61.

that aluminum alloys can be used, for example, in the construction of seacraft hulls operating at moderately high velocities, but not for seawater pump applications.

Aluminum alloys have high thermal conductivities, which should make them very attractive for heat transfer surfaces, for example, in seawater heat exchanger applications. However, several factors limit their widespread utility. For example, aluminum alloys are highly susceptible to galvanic corrosion when coupled to components made of cathodic materials such as copper-based alloys, stainless steels, nickel-based alloys, and titanium alloys. Even if they are electrically isolated, only tens of ppb levels of copper ions (e.g., generated by self-corrosion of copper-based alloys upstream) are sufficient to cause severe corrosion by the cementation mechanism<sup>161</sup> (also known as deposition corrosion). Aluminum alloys are prone to biofouling such that sufficient velocities would be required to prevent crevice corrosion under macrofouling attachments.

An extensive study was performed in simulated seawater on galvanic corrosion rates determined from current density measurements for a number of aluminum alloys coupled to dissimilar materials as well as between the aluminum alloys themselves.<sup>162</sup> The data showed that all of the aluminum alloys tested were incompatible with Cu, Ag, and Ni. In addition, alloys 1100, 6061, and 7075 were not compatible with all the stainless steels, nickel alloy 718, low alloy steel 4130, and Ti-6Al-4V. However, surprisingly, alloy 2024 and 2219 were compatible with these materials (low alloy 4130 excepted). The aluminum alloys were compatible with each other except alloy 1100 with alloy 7075. In another test, alloy 5086-H32 incurred accelerated attack when coupled to carbon steel, 90/10 CuNi, Type 304 stainless steel, and 60/40 brass.<sup>163</sup> The degree of galvanic attack is influenced by the anode/cathode area ratio. Laboratory tests<sup>164</sup> have confirmed that increasing seawater velocity will increase galvanic attack on aluminum alloys in seawater because the most common cathodic reaction is oxygen reduction, which is under diffusion control.

Pure Al is generally considered resistant to stress corrosion cracking (SCC) in seawater. Aluminum 5xxx alloys are prone to intergranular SCC failure when the Mg addition is >5% which results in supersaturation and allows precipitation of a continuous  $Mg_2Al_3$  intermetallic phase at the grain boundaries; this phase is anodic to the matrix. Restricting the Mg addition to <4% results in discontinuous  $Mg_2Al_3$  phase and SCC resistance. This was

confirmed by immersion tests in seawater.<sup>165</sup> In Mg additions >5%, addition of small amounts of Bi, Cr, Zr, B, and Be have been found to enhance SCC resistance. Alloy 6061 in the fully aged T6 temper is resistant to SCC in seawater.<sup>165</sup>

Several of the highest strength 7xxx aluminum alloys were found to be susceptible to SCC in natural seawater,<sup>166</sup> especially in the T6 temper to attain maximum strength.

Lithium additions lower the density of the aluminum alloy but increase strength and elastic modulus. However, fracture toughness and SCC resistance are lowered.

Alloy 6061 is susceptible to SCC in the T4 temper if slow quench follows high heat treat temperature. However, the T6 temper (fully aged) imparts high SCC resistance.

Exfoliation is a form of corrosion that occurs along grain boundaries in rolled aluminum alloy sheet and plate products. Corrosion often initiates at exposed grain boundaries (end-grain attack) or at pit sites that have exposed the elongated grain microstructure to the environment. The voluminous corrosion products of aluminum,  $Al(OH)_3$ , introduce internal stresses that are sufficiently to cause exfoliation, that is, lifting off of material in layers that comprise corrosion products and unaffected metal. Exfoliation resistance is derived from the absence of second phase precipitates, especially at grain boundaries, and where the free corrosion potentials of the precipitates and matrix are closely matched. The 5xxx aluminum alloys are resistant to exfoliation in seawater at Mg additions <3%. 6xxx series are resistant to intergranular corrosion (IGC) except when excess Si is present. Al alloys 5456-H116 and H117 have been used for boat hull plates to resist IGC in H321 temper.

As-quenched T3 or T-4 tempers, or naturally aged 2xxx alloys are prone to SCC and exfoliation, but only slightly to IGC, whereas 7xxx alloys are more susceptible to IGC. Overaging to T6 and T8 tempers improves SCC and exfoliation resistance but not IGC. As for 2xxx alloys, rapid quenching and overaging increases resistance significantly, for example, 7075-T63 and T-73, 7178-T76.

Cathodic protection can mitigate SCC of aluminum alloys when they are polarized to a potential in the -1.2 to -1.4 V (SCE) range. However, overprotection, for example, with Mg anodes, and especially quiescent conditions raise the surface pH significantly as  $OH^-$  ions accumulate at the aluminum alloy surface. The high-pH conditions can result in 'cathodic corrosion' of the aluminum alloy by the

formation of an aluminate complex:

Seawater flowing at moderate velocities can prevent build-up of  $\text{OH}^-$ , and hence reduce risk of cathodic corrosion. Even in quiescent conditions, the cathodic corrosion issue for aluminum alloys can be almost entirely eliminated by the use of zinc anodes for cathodic protection.

Aluminum is an active metal in the galvanic series. Therefore, in principle, it could be considered for cathodic protection of carbon steel and other engineering alloys. However, the application is not straightforward. As stated earlier, a passive  $\text{Al}_2\text{O}_3$  film usually forms on aluminum and its structural alloys. This is contrary to the requirements of a sacrificial anode material which must corrode efficiently to provide protective current for cathodic protection. Thus aluminum is alloyed with small amounts of Zn or Sn and trace levels of In or Sn (although Hg was used previously) to activate the aluminum surface. Aluminum alloys find widespread usage as sacrificial anodes in seawater, for example, on offshore platforms and pipelines because of their significant weight advantage and high current capacity ( $\text{A h kg}^{-1}$ ) compared to zinc. The development and performance of aluminum anodes have been reviewed extensively in the literature.

### 2.18.11 Magnesium

Magnesium and its alloys are not normally utilized in seawater because they are highly reactive. Reduction of DO is not normally the primary cathodic reaction, but rather the reduction of water to evolve hydrogen.

This reaction occurs particularly easily on cathodic impurities in Mg such as Fe, Cu, Cd, Zn, Ni, and so on. Being anodic and very reactive, corrosion of Mg is greatly accelerated by galvanic coupling to most other engineering materials, for example, carbon steel, stainless steels, nickel-based alloys, copper-based alloys, titanium alloys, and so on. In fact, Mg sacrificial anodes are widely used for cathodic protection of steel used in soil environments. Use of Mg for cathodic protection in seawater environments is rare because of the risk of overprotection of steel, which can cause hydrogen embrittlement in high strength steels, cathodic blistering and disbondment of coatings, and cathodic corrosion of amphoteric materials such as aluminum alloys, and high rate of self corrosion of the magnesium.

Mg alloys have been used in a very limited capacity for deep-sea diving suits – the main attraction being

very light weight due to the low density of Mg. However, the Mg has to be properly coated to prevent direct contact with seawater which would otherwise result in severe corrosion. This could be especially catastrophic at any holidays in the coating if the Mg was inadvertently coupled to a cathodic material.

The very high corrosion rate of Mg can be used to advantage in special applications, for example, ‘time release’ links on oceanographic instruments deployed in deep ocean environments.

### 2.18.12 Zinc

Although zinc is also an active metal in the galvanic series, it is much less reactive than magnesium. While the self corrosion of zinc is surprisingly low, its other major limitations are similar, that is, susceptibility to galvanic attack when coupled to steel, stainless steels, copper alloys, and so on. Historically, zinc is the most common sacrificial material used for cathodic protection in seawater.

### 2.18.13 Nonmetallic Materials

Nonmetallic materials do not generally corrode in the same manner as metals and alloys in seawater, that is, by thinning. Instead, they may suffer marine borer attack which is usually not very deep, except in wood. In addition, nonmetallics may undergo swelling and some reduction in mechanical strength – which is usually less for synthetic materials than those derived from nature (e.g., to make ropes). Deterioration is generally greater in warm seawater and close to the seabed. Other hazards are fish bites, for example, on cables. Results of long-term exposures of polymeric materials have been reviewed.<sup>167,168</sup> Nonmetallic materials are often reinforced to increase strength, for example, glass fibers in epoxy resins, carbon fibers in epoxies and aluminum, steel in concrete, and so on. Reinforcements can affect the performance of the composite material in seawater, for instance, carbon fibers can accelerate galvanic corrosion of aluminum and corrosion of steel reinforcement can lead to spalling of concrete. Rubber linings and reinforced polymer (e.g., flake glass polyester) coatings applied to metal substrates can provide corrosion protection. However, elastomers exhibit reduction in elongation with prolonged exposures; silicone–rubber and ester-based polyurethanes deteriorate more extensively. Thus, meticulous attention to selection, application, inspection, and maintenance is essential for successful

usage. While they may provide adequate corrosion protection, the major limitations of polymeric materials include elevated service temperatures, high pressure containment, and fatigue life.

For seawater service, concrete with sulfate resistance (Type V cement) must be specified. The steel reinforcement requires corrosion protection for long-term performance, for example, by cathodic protection. Ceramics are generally considered resistant to seawater.

### 2.18.14 Corrosion Protection Methods

In principle, most of the methods used for corrosion control in other aqueous environments are applicable to seawater. However, the major factors contributing to the corrosivity of seawater that must be taken into consideration include high chloride and sulfate content, presence of microorganisms, biofouling, and putrefaction.

Carbon steel corrodes in aerated seawater at rates that require either a corrosion allowance or other means of corrosion control if a long service life is required. Corrosion allowance requires careful monitoring to avoid unexpected failures. It is probably most useful for applications where some areas of localized perforation caused by seawater can be tolerated without loss or mixing of fluids, or reduction in structural (load-bearing) properties, for example, nontubular structural support members.

Coatings are the most common method of corrosion control. Apart from suitability for seawater service, the single most important requirement for a successful coating is proper surface preparation and application conditions – which are often best achieved under shop conditions. Once a coating system is applied, even under initially optimal conditions, repairing or replacing it in service can be extremely challenging. For applications such as the underwater areas of ship hulls, it is fairly easy to perform coating inspections, repairs, and replacements during periodic dry docking. In the case of fixed structures, such as offshore platforms and pipelines, similar access to the underwater areas is almost impossible. Building cofferdams around the structure and evacuating them to carry out repairs and replacements can only be done more economically in very shallow waters. Although some coatings that can be applied underwater (e.g., by divers) are available, they are fraught with problems, for example, surfaces cannot usually be adequately cleaned and prepared, and coating application and inspection are very difficult.

Hence, such coatings are typically only considered for emergency situations. Antifouling coatings are utilized on ships for controlling macrofouling. Presently, most antifouling coatings contain either copper or cuprous oxide as the antifouling agent. Other coatings based on low surface energy are also available to minimize adhesion of macrofouling, but they are more expensive. Both types of coatings are consumed with time and lose their effectiveness, and thus need replacement periodically.

As mentioned previously, it is possible to protect simple structural steel shapes by sheathing. For example, splash-zone areas on offshore platforms have been successfully protected by alloy 400 (nickel–copper) or 90/10 CuNi sheathing. Hot risers are not usually protected by sheathing because of periodic visual inspection requirements that would require removal of the sheathing. Metallurgically cladding steel with a more corrosion resistant alloy can also be used but is again applicable to only relatively simple geometries such as piping.

The most widely used method for corrosion control of steel structures immersed in seawater is cathodic protection using sacrificial zinc or aluminum anodes. Cathodic protection is only effective below the waterline, regardless of tide level. Cathodic protection and coatings complement each other if they can be used together for corrosion control. The coating reduces the area of metal requiring protection; conversely, cathodic protection can extend the coating life. However, it is essential to select a coating that is compatible with cathodic protection to obviate cathodic disbondment (blistering) of the coating. The anode material must meet tight alloy composition and performance requirements before it is specified. Sacrificial anodes generally require no maintenance, except replacement when consumed. However, it must be recognized that replacement of anodes on stationary structures is difficult and very costly; thus, in such cases, the original anodes are typically designed to last the life of the structure (e.g., 30 years). Impressed current cathodic protection systems serve the same function but, contrary to popular belief, require more attention, for example, in monitoring proper operation of rectifiers and reference electrodes, especially for systems with automatic control, stray current effects, diver safety concerns, and so on. Impressed current anodes based on platinized niobium are now preferred in seawater over platinized titanium because of the much higher breakdown voltage of niobium ( $\sim 70$  V) compared to titanium ( $\sim 9$  V). Cathodic protection of structures

and components in seawater is extensively covered in the published literature.

Calcareous deposits (discussed previously), formed in seawater on cathodically protected metal surfaces are essential for polarization of the structure, and to achieve significant reduction in current demand by the structure. Although used extensively for carbon steels, cathodic protection can also be used to mitigate corrosion of nonferrous materials in seawater, for example, for pitting and crevice corrosion of stainless steels. In fact, carbon steel can be used as sacrificial anode material. Cathodic protection can also be effective for controlling galvanic corrosion between dissimilar materials, for example, between waterbox, tube sheet, and tubes; and erosion-corrosion of copper alloys, for example, inlet-end impingement in heat exchangers.

Cathodic protection for corrosion control in the interior of pipes has been investigated but is not commonly used for a variety of reasons. The biggest problem is limited 'throwing power' of the protective current. Thus, depending on pipe size, an anode may be required, say, every few meters for protecting bare steel. Continuous anodes along the length of the pipe for internal cathodic protection have also been investigated but present many limitations including economics.

Modification of the seawater by deoxygenation is an effective method of corrosion control. As discussed previously, it is used in a number of applications, for example, MSF desalination and seawater injection during secondary recovery. For steels, while corrosion rate decreases with oxygen content, it increases markedly at elevated temperatures even when only a few hundred parts per billion oxygen is present. Thus, effective control and monitoring of oxygen is essential for this method of corrosion control, especially at high temperatures. Deaeration has not been found to be harmful for passive materials such as stainless steels that often rely on oxygen for film healing.

Conflicting requirements often preclude use of a single material in most engineering applications. Since dissimilar materials are often unavoidable, the issue of galvanic corrosion must be addressed. In principle, electrical isolation between anode and cathode members can be effected by using nonconductive (insulating) hardware to mitigate galvanic corrosion. However, in many applications, this is difficult to achieve because alternative electrical grounding paths exist, for example, hangers or pedestal supports in piping systems. In many systems, however, even if electrical

isolation is possible, it is not permitted for personnel safety reasons, for example, electrical safety codes may preclude galvanic isolation in systems where ground fault currents would otherwise pose potential electrical shock hazards. In design, a small cathode/anode area ratio is usually selected to minimize galvanic corrosion. Coating either the cathode or both the cathode and anode can be a practical means of controlling galvanic corrosion. The anode alone should not be coated since inevitable holidays and flaws in the coating can severely accelerate corrosion attack at those locations because of the resulting very adverse anode/cathode area ratio. However, it should be recognized that coatings for galvanic corrosion control have limitations where they are difficult to apply and maintain, and where they can incur damage rather easily, for example, in pumps.

Mitigation of galvanic corrosion in piping systems at dissimilar-metal flanged-joints, without electrical isolation, has been addressed in a number of ways. Since the galvanic corrosion damage of the anodic material is restricted over a relatively short distance that is either known from experience or can be determined by mathematical modeling, one approach is to insert a heavier-wall waster spool between the original anode and cathode. The length of the spool piece is a function of the pipe diameter and polarization characteristics of the cathode.<sup>169</sup> Consumption of the waster spool piece can be monitored, for example, by ultrasonic thickness gauging from the outside, so that it can be replaced in a timely manner. A novel technique known as the 'bi-electrode' method<sup>170,171</sup> has been proposed to control galvanic corrosion. Two ring or sleeve electrodes with inert metal surfaces are inserted in the piping system on either side of the joint. The sleeves which are electrically isolated from the piping system are polarized with respect to each other by an external DC power supply, such that the electrical field created by current flow annuls the galvanic current. Since the galvanic current can vary with operating conditions such as flow, temperature, oxygen content, and so on, the externally applied counter current between the bielectrodes has to adjust automatically – a problem that has been found to be challenging to date.

For many components, coatings and/or cathodic protection are not practical methods of corrosion control, for example, pumps, valves, entire heat exchanger tubing in shell-and-tube heat exchangers, plates in plate-and-frame heat exchangers, internal piping, and so on. In such cases, corrosion resistant materials must be selected. The selection is based on

practical experience and test data. For example, as discussed earlier, Type 304 and 316 stainless steels are unsuitable materials for seawater service because of extreme susceptibility to crevice corrosion in aerated seawater; in other words, they should not be used for immersion service in seawater without protection (e.g., cathodic protection) if crevices are present. The use of a resistor-controlled cathodic protection system has been proposed for controlling internal corrosion in chlorinated stainless steel piping systems.<sup>172,173</sup>

Unfortunately, selection of more highly alloyed grades such as Type 317 stainless steel or alloy 825 that contain greater amounts of Cr and Mo does not bestow sufficient resistance to crevice corrosion. Crevice corrosion initiation time is usually longer in cold seawater. Conversely, it is known that localized corrosion susceptibility increases with increasing temperature. Critical pitting and critical crevice corrosion temperature data are used to provide guidelines for the upper limits of alloys. For example, it is generally recommended that superaustenitic 20Cr–25Ni–6Mo stainless steels should not be subjected to seawater temperatures  $> \sim 35^{\circ}\text{C}$  for prolonged periods. Pitting resistance equivalent numbers (PREN) based on alloy composition (primarily Cr, Mo, and N) have been advocated as indicators of localized corrosion resistance of stainless steels and nickel-based alloys in seawater and other chloride environments. However, crevice corrosion resistance does not depend just on alloy content; it is also affected by crevice geometry, tightness, depth, crevice-forming materials, their deformability, and surface finish of both the crevice formers and the alloy in question.<sup>174</sup> Thus, although many materials, such as Ni–Cr–Mo–Fe alloy C-276, have very high resistance to crevice corrosion in seawater, they are by no means completely immune under all crevice conditions. This is also the case with titanium, which is very resistant to localized attack in seawater at ambient temperatures, but is susceptible to crevice corrosion at  $> 70^{\circ}\text{C}$ . Titanium alloys containing noble metals additions, such as palladium in grade 7, are more resistant to crevice corrosion.

Copper–nickel alloys have been successfully used for heat exchanger piping, waterbox and sheathing applications in clean seawater. In the freely corroding condition, they are resistant to macrofouling but not entirely immune. Their major limitations are high susceptibility to accelerated corrosion by sulfides, for example, in polluted seawater and bottom silt; or generated *in situ* as a result of putrefaction of stagnant

seawater by sulfate reducing bacteria. Avoiding contact with polluted seawater is difficult in certain situations, for example, when shipboard piping and heat exchangers are commissioned in harbors. Guidelines based on practical experience suggest that the risk of sulfide production and consequent initiation of corrosion of copper–nickel alloys increases when they are exposed to stagnant seawater in closed systems for more than  $\sim 2$  days. Thus, it is imperative that such conditions be avoided by draining the system, flushing with fresh water and drying, if possible. Alternatively, the water can be treated with suitable biocides that are compatible with the alloy. Nickel aluminum bronze pumps have been used successfully in unpolluted seawater. This is not a good choice of material for auxiliary pumps because of the risk of seawater putrefaction during protracted standby periods and hence sulfide attack. However, heat treatment is necessary to preclude dealloying, especially in the heat-affected zones associated with welds, and the consequent increased risk of fatigue cracking. Such areas are often beyond the reach of cathodic protection from bare steel piping that might be beneficial in other situations where the current ‘throwing power’ is more effective.

Other factors that need to be considered in the selection of copper-base alloys include sensitivity to erosion–corrosion at high flow rates and galvanic corrosion when coupled to stainless steels, titanium, and Ni–Cr–Mo alloys. For instance, copper–nickel heat exchanger tubes that have suffered from sulfide and/or erosion–corrosion attack are often retubed with titanium. This results in unacceptable galvanic corrosion of the copper–nickel tube sheet. This situation is usually alleviated by the application of cathodic protection which must be controlled and monitored carefully to preclude hydriding of the titanium tubes that can be caused by overprotection. Tube support plate spacing also has to be addressed to preclude vibration of the low-modulus, thin-walled titanium tubes, and subsequent mechanical fatigue failure.

Chlorination is widely used for controlling biofilms and macrofouling; the latter interferes with seawater flow. Both biofouling and macrofouling can initiate corrosion of engineering materials such as many stainless steels, nickel–copper alloys, and even some copper-based alloys. At low levels,  $\sim 0.5$  ppm residual, chlorine does not accelerate corrosion of these materials or carbon steel significantly. However, as the chlorine concentration increases to  $\sim 1$ – $2$  ppm, risk of general corrosion on the active metals and localized corrosion on certain passive metals

increases. Reduction of galvanic corrosion of certain materials, for example, copper-alloys coupled to stainless steels and nickel alloys, has been observed especially in laboratory tests and explained on the basis of biofilm suppression and attendant reduction reaction kinetics on the cathode. As the chlorine content increases to ~5 ppm or more, corrosion propensity of many stainless steels and nickel-copper alloys increases noticeably. Titanium is unaffected by even very high levels of chlorine in seawater – in fact, titanium electrodes are commonly used in the electrolytic cells to generate chlorine from seawater.

## 2.18.15 Test Methods

Test methods for assessing materials performance in seawater are extensively described in the literature and standards. In principle, most of these test methods are not applicable exclusively to seawater. However, it is important to recognize the important differences between natural seawater that contains micro and macroorganisms that can influence corrosion behavior of materials, and synthetic seawater that does not contain representative species which mimic biological effects. The equipment used for testing in seawater must also be corrosion resistant to prevent test interruptions or confounding of results by extraneous corrosion products introduced into the system.

### Glossary

**Aerobic** The presence of oxygen in an environment (including oxygen from the air).

**Anaerobic** The absence of oxygen in an environment (including oxygen from the air).

**Backfill** Material that is applied around the component that is buried.

**Bacteria** Unicellular microorganisms, typically a few micrometers in length and having many shapes including spheres, rods, and spirals.

**Biogenic** Arising from living processes.

**Brownfield site** Former commercial or industrial site, earmarked for commercial development

or industrial projects. Potentially contaminated land.

**Cathodic protection** A decrease of corrosion rate of a metal by cathodic polarization such that the net anodic current is decreased.

**Clay** Natural constituent of soil. Comprises particles of less than 0.005 mm mean diameter ( $<5\ \mu\text{m}$ ).

**Conductivity** The specific ability of a material to conduct ionic or electronic charge. In SI units, the conductivity is defined as the conductance (in Siemens or  $\text{Ohms}^{-1}$ ) between the opposing faces of a cube of side  $1\ \text{m}^2$  (SI units:  $\text{Sm}^{-1}$ ).

**Corrosion product** A species formed as a result of corrosion; most commonly a solid (e.g., rust) but may be liquid, gaseous, or ionic.

**Corrosion protection** A process of modification to a material or its corrosive environment such as to decrease its corrosion rate.

**Corrosion rate** The rate at which corrosion proceeds. It may be expressed as loss of thickness or cross-section (e.g.,  $\mu\text{m year}^{-1}$ ), as a rate of mass loss per unit area (e.g.,  $\text{g m}^{-2} \text{d}^{-1}$ ), or via Faraday's Law, as a current density (e.g.,  $\text{A m}^{-2}$ ). Although the term implies that corrosion rate is constant, this is not always the case.

**Corrosivity assessment or aggressivity**

**assessment** Estimation of likely corrosion rates that will occur on metal/alloys in a particular soil environment on the basis of consideration of soil type, resistivity, soil and groundwater chemistry, etc. Also referred to as aggressivity assessment.

**Disturbed soils** Soils that are mechanically disturbed, for example, by excavation.

**Electrical resistance (ER)** Method for measuring corrosion rate where metal loss of a probe element is determined by measurement of electrical resistance of the element.

**General corrosion or uniform corrosion** A form of corrosion that results in a more-or-less uniform thickness loss from the surface of a material.

**Graphitic corrosion** A form of corrosion of grey cast iron in which the metallic constituents are selectively removed leaving the graphite (often called 'graphitization,' although the latter term is deprecated because of its alternate use to describe the formation of graphite, for example, by the decomposition of carbides in steel).

**Greenfield site** Agricultural or forest land or undeveloped (virgin) site earmarked for commercial development or industrial projects.

**Groundwater** Natural water contained within soil.

**Hot-dip coating or galvanizing** A method of application of a coating by immersion of a material in a bath of molten metal: for example, hotdip galvanizing, for the formation of a zinc coating on steel.

**Linear polarization** (1) The approximate linear dependence between current density and

potential at low values of electrode polarization (typically less than  $\sim \pm 10 \text{ mV}$ ).

(2) An electrochemical test method that uses the principle of linear polarization to derive an estimate of the electrode reaction (e.g., the corrosion rate). Not the same as Ohm's law.

**Long-line corrosion** Form of differential concentration corrosion, occurring on pipelines crossing different soil conditions or for piles crossing different soil layers. The large surface area in benign/aerated conditions causes increased corrosion in more active/deaerated conditions. See also macro-cell corrosion.

**Macro-cell corrosion** Form of differential concentration corrosion.

**Metabolism** The complete set of chemical reactions that occur in living cells. These processes are the basis of life, allowing cells to grow and reproduce, maintain their structures, and respond to their environments.

**Microbially influenced corrosion (MIC)** A form of corrosion that is associated with the presence of microorganisms, including bacteria, fungi, and algae. Corrosion is commonly influenced by the metabolites of the organism and/or by the production of a biofilm.

**Microorganism or microbe** An organism that is microscopic (too small to be seen by the human eye). The study of microorganisms is called microbiology. Microorganisms can be bacteria, fungi, archaea, or protists, but not viruses and prions, which are generally classified as nonliving.

**Moisture-holding capacity of a soil** A term applied to the ability of a soil to hold water present in the form of capillary water.

**Nondisturbed soils** Soils in the natural state that have not been affected by excavation.

**pH** The negative logarithm of the hydrogen ion activity defined as  $\text{pH} = -\log_{10} a_{\text{H}^+}$ , where  $a_{\text{H}^+}$  is the activity of the hydrogen ion in an electrolyte.

**Pit** A cavity in the surface of a material that extends into its interior.

**Pitting (corrosion)** A form of localized corrosion that results in the formation of pits, often associated with a cover of corrosion product or perforated metal over the pit.

**Polarization resistance** The slope ( $dE/di$ ) at the corrosion potential of the current density versus electrode potential under Linear Polarization. The polarization resistance is inversely proportional to the corrosion rate provided that charge transfer is the controlling electrode reaction. See also Charge Transfer Resistance.

**Redox** An abbreviation for reduction–oxidation.

**Redox potential** The equilibrium potential of an inert electrode (such as platinum) in a solution; a measure of the oxidizing or reducing tendency of the solution.

**Reference electrode** An equilibrium half-cell electrode of reproducible potential against which an unknown electrode potential can be measured. Commonly used examples include the standard hydrogen electrode (Pt,  $H_2/H^+$ ), the calomel electrode ( $Hg/Hg_2Cl_2/Cl^-$ ), and the silver/silver chloride electrode ( $AgCl/Cl^-$ ).

**Resistivity** The inverse of the conductivity of a material or solution.

**Sabkha** A flat area between a desert and an ocean, characterized by a crusty surface consisting of evaporite deposits (including salt, gypsum, and calcium carbonate), windblown sediments, and tidal deposits.

**Sand** Natural constituent of soil. Comprises particles of mean diameter 0.07–~2 mm in size (70–2000  $\mu m$ ).

**Selective backfill** Backfill material that has been selected to exhibit specific properties, particularly material of low corrosivity.

**Silt** Natural constituent of soil. Comprises particles of mean diameter 0.005–0.07 mm (5–70  $\mu m$ ).

**Sulfate-reducing bacteria (SRB)** Term describing several groups of anaerobic bacteria that use sulfate as an oxidizing agent for their energy-generating metabolism, reducing it to sulfide, which appears as  $H_2S$ , sulfide ions, metal sulfides, or a combination of these forms according to the conditions.

**Standard hydrogen electrode (SHE)** A redox electrode which forms the basis of the thermodynamic scale of oxidation–reduction potentials. The potential of platinum electrode in an acid solution with  $aH^+ = 1 \text{ mol kg}^{-1}$ , purged with hydrogen at a pressure of 101 325 Pa, which is declared to be zero at all temperatures.

**Stray-current corrosion** A corrosion process caused by unwanted currents flowing through paths other than the intended circuit and usually arising from an adjacent direct current source (e.g., traction supply, welding station, cathodic protection supply) or from an induced alternating current source (e.g., power transmission conductors).

**Substrate** (1) The base material on which a coating is present. (2) Any substance (other than materials required in trace quantities only) required for the growth or metabolism of a microorganism.

**Thermal spraying** A process for the application of a coating to a substrate by forming an atomized spray of small particles of molten material and directing onto a substrate with a suitable profile.

**Underground corrosion** A process involving corrosion of a buried material where the earth's soil forms a component of the corrosive environment.

Corrosion in soils (also referred to as ‘underground corrosion’) is applicable to a wide range of different components (e.g., pipelines, underground storage tanks, tubular and sheet steel piles, ground anchors, power and telecommunication cables, etc.), which are either directly buried, driven, or otherwise positioned underground (sometimes referred to as ‘below grade’) and which can, therefore, be exposed to a wide range of different conditions (ranging from dry aerated sand to water-logged anaerobic clay). Any consideration of the subject of corrosion in soils must address both natural and contaminated (‘green field’ and ‘brown field’) sites and must consider ferrous alloys (such as cast iron, ductile iron, carbon/low-alloy steels, various stainless steels), as well as alloys of copper, aluminum, zinc, and lead. It must also include the performance of metallic coatings (e.g., galvanizing and thermally sprayed coatings). However, in all cases, the basic corrosion mechanisms are the same as for corrosion in natural waters. Examples of corrosion in soils for different components are shown in Figures 1–4.

Degradation of buried nonmetallic components (such as polyvinyl chloride (PVC) or high density polyethylene (HDPE) pipe) and concrete (including corrosion of reinforcing steel in buried concrete foundations) are not considered here.

**Figure 1** Corrosion of cast iron pipe (due to external stray current).

**Figure 3** Corrosion of buried copper pipe exposed to  $\text{H}_2\text{S}$  containing ground water. Reproduced from *Corrosion Atlas*, 3rd ed.; compiled by Durning, E. D. D.; Elsevier Science Publishers: London, 1997; (Item 06.05.05.01).

**Figure 4** Bronze spearheads (Knossos, Crete, ca. 1500 BC).

The main aspect that differentiates corrosion in soils from corrosion in other natural environments is the contribution that the soil (and associated ground water) plays in modifying the corrosion mechanism and in particular the corrosion rate. In practice, cast iron, ductile iron, and carbon/low-alloy steels behave essentially in the same manner for a given soil type and condition; their corrosion rates can range from negligible ( $<0.005 \text{ mm year}^{-1}$ ) to extremely rapid (with localized corrosion of  $>1 \text{ mm year}^{-1}$ ). The differences are related to soil type, soil resistivity, ground water composition, soil condition, and the activity of bacteria, especially sulfate-reducing bacteria (SRB).

It is not the intention here to provide full details of soil genesis, for which the reader is directed to specialist publications<sup>1</sup> for a detailed description. However, an outline description of different soil types and methods of classification is included, in order to assist in the understanding of the variations in soil that directly relate to the corrosion processes.

Corrosion in soils has been studied worldwide over many years; to date, the most extensive and comprehensive study was conducted by Romanoff, for the National Bureau of Standards (NBS) in the US in the 1950s and 1960s. This work was published as a series of NBS circulars and presentations,<sup>2,3</sup> covering the results of over 37 000 different samples, comprising numerous different metals/alloys and 95 different soils, exposed for up to 17 years. The work is still relevant today as the benchmark for describing performance of various metals and alloys exposed to a wide range of soils and is the ultimate source for much of the published data relating to the subject.

Other studies have been carried out since the work by Romanoff up to the present day in North

America,<sup>4,5</sup> the United Kingdom,<sup>6,7</sup> Sweden,<sup>8</sup> Germany,<sup>9</sup> and Russia<sup>10</sup> and elsewhere. Whilst these different studies provide further information on specific local soils and on alternative/new alloys, the overall results are complementary to the original findings of Romanoff.

The original studies of corrosion in soil mainly concerned pipelines; this was later expanded to include driven piles. However, since the 1980s significant interest has also been focused on underground storage tanks, because of increased concern about environmental damage caused by leaking tanks, especially for small scale (retail) storage facilities at petrol (gasoline) stations, domestic fuel storage facilities, etc. The long-term performance of ground anchorage systems (high stressed anchorages, soil nails, tie-bars, etc.) is another area where there is an increasing requirement to demonstrate long-term performance, especially for systems that provide stabilization for major critical civil structures such as flood defense, dams, bridges, tunnels, etc.

In archaeology, the extent of deterioration of metals over millennia of exposure is of interest. The condition of bronze and iron artifacts can vary greatly depending on local ground conditions.

## 2.19.2 The Nature of Soils

Encarta Dictionary defines soil as “The top layer of most of the Earth’s land surface, consisting of the unconsolidated products of rock erosion and organic decay, along with bacteria and fungi.” While demonstrating the natural variability in soils, such a definition does not fully convey an impression of the countless variations in soil that occur. The type and condition of the soil are directly affected by moisture, principally entering through rainfall, but also from flooding, tidal action, and human interaction (e.g., from irrigation schemes, dewatering, or land reclamation schemes), as well as by contamination from industrial processes. It is the combination of the genesis of the soil and the source of moisture within the soil that leads to variations in soil chemistry.

Often locations are classed as ‘green field’ or ‘brown field’ sites; green field sites are those where there has been no previous industrial use, while brown field sites are locations of former industrial use (factories, storage yards, waste tips, etc.). For brown field sites there is, therefore, also the possibility that contaminated soil may be present, the soil being contaminated by the presence of man-made chemicals or

other human alteration in the natural soil environment. In addition to the direct discharge of industrial wastes to the soil, contamination often occurs from the rupture of underground storage tanks, application of pesticides, percolation of contaminated surface water, oil dumping or leaching of wastes from landfill sites. The most common chemicals involved are petroleum hydrocarbons, pesticides, and heavy metals.

An important consideration is that statutory or other routine surveys of contaminated land for data acquisition are carried out primarily for public health and environmental reasons and are rarely, if ever, intended for corrosivity assessment. Most of the data, thereby, generated are of little or no consequence for soil corrosivity evaluation, whereas other data of vital importance for appraisal of soil corrosivity are often not generated by such surveys. A soil corrosivity survey is, therefore, a distinct exercise from a general contaminated land survey.

### 2.19.2.1 General Soil Texture and Structure

In any assessment of potential corrosivity, it is important that the nature of the soil itself is considered; however, this is a vast topic.<sup>1</sup> The more important aspects on soil texture and structure that follow are based on the corresponding chapter, by Harris and Eyre, in the previous edition.<sup>11</sup>

Soils are commonly named and classified according to the general size range of their particulate matter. Thus, sandy, silt, and clay types derive their names from the predominant size range of inorganic constituents. Particles between 0.07 mm and ~2 mm are classed as sands. Silt particles range from 0.005 to 0.07 mm, and clay particle size ranges from 0.005 mm mean diameter down to that of colloidal matter.

The proportion of the three size groups will determine many of the properties of the soil. Although a number of systems have been used to classify soils according to texture, the one shown in **Figure 5** represents the most commonly used terminology for various proportions of sand, silt, and clay.

As soils contain organic matter, moisture, gases, and living organisms as well as mineral particles, it is apparent that the relative size range does not determine the whole nature of the soil structure. In fact, most soils consist of aggregates of particles within a matrix of organic and inorganic colloidal matter rather than of separate individual particles. This aggregation gives a crumb-like structure to the soil and leads to friability, more ready penetration of moisture, greater

aeration, less erosion by water and wind, and generally greater biological activity. The loss of the aggregated structure can occur as the result of mechanical action, or by chemical alteration such as excess alkali accumulation. Destruction of the structure or 'puddling' greatly alters the physical nature of the soil.

Mention should be made of the soil profile (section through soil showing various layers) because it is important to recognize that the soil's surface gives a very poor indication of the underlying strata. Pipelines are buried a meter or so and foundations/anchorages typically more than 10 m below surface soils and corrosion surveys based on surface observations give little information as to the actual environs of the pipe when buried.

### 2.19.2.2 The Clay Fraction

Clays make up the most important inorganic constituents of soil. They consist of various minerals depending on the mineral composition of the parent material, and on the type and degree of weathering. Often clays may be grouped in a family series, depending upon the weathered condition, as, for example, montmorillonite → illite → kaolinite. Weathering of montmorillonite causes loss of potassium and magnesium, which alters the crystalline structure, and eventually kaolinite results. In this example (and also for other clay mineral groups) marked changes occur in the physical properties of a soil as clay minerals undergo the weathering process.

Montmorillonite clays absorb water readily, swell greatly, and confer highly plastic properties to a soil. Thus soil stress occurs most frequently in these soils and less commonly in predominantly kaolinitic types. Similarly, a soil high in bentonite will show more aggressive corrosion than a soil with a comparable percentage of kaolinite. A chalky soil usually shows low corrosion rates. Clay mineralogy and the relation of clays to corrosion deserve attention from corrosion engineers.

### 2.19.2.3 Aeration and Oxygen Diffusion

The pore space of a soil may contain either water or a gaseous atmosphere. Therefore, the aeration of a soil is directly related to the amount of pore space present and to the water content. Soils of fine texture due to high clay content contain more closely packed particles and have less pore capacity for gaseous diffusion than an open-type soil such as sand.

Oxygen content of soil atmosphere is of special interest in corrosion. It is generally assumed that the

**Figure 5** Proportions of sand, silt and clay making up the various groups of soils classified on the basis of particle size <sup>(\*)</sup>. Reproduced from *Soil Survey Manual* 1993. Soil Conservation Service. U.S. Department of Agriculture Handbook 18. United States Government Printing Office, Washington, DC. (ISBN-10: 1410204170) (<http://soils.usda.gov/technical/manual/>).

<sup>(\*)</sup> The corresponding percentages of clay, silt, and sand present in the soil are located on relevant axis of the triangle.

The values are then projected inwards (along the lines as indicated on the axis). The name of the area in which the lines intersect is the class name for the particular soil. For example, a soil with 50% clay, 30% silt, and 20% sand (location ❶) is a 'clay,' while a soil with 30% clay, 20% silt, and 50% sand (location ❷) is a 'sandy clay loam,' etc.

gases of the upper layers of soil are similar in composition to the atmosphere above the soil, except for a higher carbon dioxide content. However, biological activity within the soil tends to decrease the oxygen content and replace the oxygen with gases from metabolic activity, such as carbon dioxide. Most of the biological activity occurs in the upper 150 mm of soil, and it is in this region that diffusion would be most rapid. Factors which tend to increase microbial respiration, such as the addition of large amounts of readily decomposed organic matter, or factors which decrease diffusion rates (water saturation) will lead to development of anaerobic conditions within the soil. Anaerobic conditions favor the proliferation of SRB, which produce hydrogen sulfide, sulfide ions, or inorganic sulfides according to the conditions and may give rise to very high rates of localized corrosion under conditions of near neutral pH and low oxygen concentration,

which would normally be considered benign. Such situations are discussed in [Section 2.19.2.6](#) below.

The main difference between 'buried' and 'driven' components relates to the availability or otherwise of oxygen. Where the components are exposed to 'back-fill,' the soil will normally be aerated (at least initially), whereas for driven components (i.e., where the item is placed in 'undisturbed soil') the oxygen content can be negligible and in these cases corrosion of the bulk of the item will also be negligible (see [Section 2.19.3.5](#) below).

#### 2.19.2.4 Water Relations

No soil corrosion occurs in a completely dry environment. Water is needed for ionization of the oxidized state at the metal surface. Water is also needed for ionization of soil electrolytes, thus completing the

circuit for flow of a current maintaining corrosive activity. Apart from its participation in the fundamental corrosion process, water markedly influences most of the other factors relating to corrosion in soils. Its role in weathering and soil genesis has already been mentioned.

#### **2.19.2.4.1 Free ground water**

At some depth below the surface, water is constantly present. This distance to the water table may vary from a <1 m to >100 m, depending upon the geological formations present. Only a small amount of the metal used in underground service is present in the ground water zone. Such structures, as well as casings and under-river pipelines, are surrounded by ground water. The corrosive conditions in such a situation are essentially those of an aqueous environment.

#### **2.19.2.4.2 Gravitational water**

Water entering soil at the surface from rainfall or some other source will tend to move downwards. This gravitational water will flow at a rate governed largely by the physical structure regulating the pore space at various zones in the soil profile. An impervious layer of clay, a 'puddled' soil, or other layers of material resistant to water passage may act as an effective barrier to the gravitational water and cause zones of water accumulation and saturation. This is often the situation in highland swamp and bog formation. Usually, gravitational water percolates rapidly to the level of the permanent ground water.

#### **2.19.2.4.3 Capillary water**

Most soils contain considerable amounts of water held in the capillary spaces of the silt and clay particles. The actual amount present depends on the soil type and weather conditions. Capillary moisture represents the important reservoir of water in soil, which supplies the needs of organisms living in or on the soil. Only a portion of capillary water is available to plants. The moisture-holding capacity of clay is much greater than that of a sandy type soil. Likewise, the degree of corrosion that occurs in soil will be related to its moisture-holding capacity, although the complexities of the relationships do not allow any direct and simple quantitative predictive application.

#### **2.19.2.5 Variable Conditions**

An important aspect of corrosion in soil is the effect that varying soil type and composition have on corrosion, giving rise to different conditions on different sections of a buried structure; this could be due to

changes in moisture content, soil structure (clay to sand), or soil chemistry (pH, chloride concentration, oxygen content, etc.), resulting in galvanic corrosion.

For horizontal systems (i.e., pipelines, metallic cable sheaths, etc.), such processes are often referred to as 'long-line corrosion' where the pipeline crosses from one soil condition to another. Vertical changes in conditions are equally important, principally for driven components (such as piles or soil nails). The effect can be extensive, with the section of a structure in the higher pH, low chloride, or more aerated ground acting as a large cathode over tens or even hundreds of meters in length, leading to accelerated corrosion in the lower pH, deaerated, or higher chloride areas. A classic example is that of a pipeline running in normally high resistance, well aerated sand crossing an area of *sabkha* (i.e., salt rich desert area). *Sabkha*, being very high in salt content and generally low resistivity ground, is naturally more corrosive than the surrounding sand and hence would result in naturally higher corrosion rates. However, for a continuous pipeline, the line sections in the adjacent, normal sand also act as a good cathode, increasing the rate of attack in the *shabka* area.

#### **2.19.2.6 Effect of Bacterial Activity on Corrosion in Soils**

Microorganisms or 'microbes' are commonly defined as living entities that are too small to be visible to the human eye. Soils that contain more than a few percent moisture abound with an incalculable variety of microbial activity. However, fundamentally, the vast majority of those microbes perform a single overall metabolic function to mineralize organic matter of plant and animal origin and ultimately to convert it to carbon dioxide, inorganic nitrates, inorganic phosphates, etc. Such microbes, termed 'heterotrophs,' have little direct relevance to corrosion of buried metal.

A more detailed account of microbially-influenced corrosion (MIC) is presented in **Chapter 2.20, Corrosion in Microbial Environments** of this work, to which the reader is referred. In the context of soils, the most important group of microorganisms associated with corrosion belongs to the specialized group of bacteria known as sulfate reducing bacteria (SRB); the vast majority of MIC failures are related to their activities.

SRB thrive in oxygen-free soils and other anaerobic environments, where they obtain their required carbon from organic nutrients and their energy from the reduction of sulfate ions to sulfide. Waterlogged

soils often provide ideal environments for SRB proliferation, especially in brackish or estuarine water areas, which contain abundant sulfate ions. Sulfide appears as hydrogen sulfide ( $\text{H}_2\text{S}$ ), sulfide ions, metal sulfides, or a combination of these according to conditions. Sulfides are highly corrosive to many metals, mainly because they form complex semiprotective layers that are also conductive and cathodic to the parent metal, leading to intense localized (shallow pitting) attack in areas of film breakdown. In the case of ferrous metal corrosion, the characteristic black iron sulfide ( $\text{FeS}$ ) corrosion products liberate  $\text{H}_2\text{S}$  on acid treatment, distinguishing it from black iron oxide (magnetite). The corrosion products are often loose and when dislodged exhibit pits lined with bright metal corresponding to areas of anodic dissolution, but are sometimes also hard and adherent. Typical pictures of the morphology of this type of attack are shown in **Chapter 2.20, Corrosion in Microbial Environments**.

The effect of high SRB activity to corrosion rates in soils and corrosivity assessments are described in the relevant sections of this chapter (below). Suffice to say at this point that the most severe conditions with respect to MIC typically occur under conditions of low oxygen content and near-neutral pH, which would be otherwise regarded as benign. In this respect, low oxidation/reduction (redox) potential is an important indicator of intense SRB activity.

## 2.19.3 Corrosion Rates in Soils

### 2.19.3.1 Carbon and Low Alloy Steels

The monumental work of Romanoff,<sup>2</sup> which still forms the basis of much of our understanding of corrosion in soils, demonstrated that, in practice, all ferrous alloys (cast iron, wrought iron, mild steel, low carbon steel, etc.) are attacked at essentially the same rate in a particular soil. However, the rate of attack is not normally linear with time and can generally be modeled by an exponential relationship, as shown in eqn [1]:

$$W = k_w \cdot t^m \text{ or } P = k_p \cdot t^n \quad [1]$$

where  $t$  is period of exposure (years);  $W$ , uniform metal loss (measured as mm, mil,  $\text{g m}^{-2}$  or  $\text{oz ft}^{-2}$ );  $P$ , pit depth (mm or mil);  $k_w$ ,  $k_p$ , scale constants (mm, mil,  $\text{g m}^{-2}$  or  $\text{oz ft}^{-2}$ );  $m$ ,  $n$ , shape constants, with  $n$ ,  $m \leq 1$  (typically  $n$ ,  $m \approx 0.33$ – $0.67$ ).

The scale and shape constants are dependent on the soil. For example, data for different ferrous materials exposed to two different soil types (sand and

clay respectively) over a 17 year period are shown in **Figure 6**, which presents both the raw data and the calculated regression lines for the two conditions. The shape constants are 0.702 in clay and 0.809 in sand (independent of units), with scale constants of 0.636 and 0.215 mm for clay and sand, respectively. The error bands shown in **Figure 6** are the 95% prediction range from linear regression analysis of the data which gives factors of  $\times 10^{\pm 0.094}$  for clay and of  $\times 10^{\pm 0.236}$  for sand. Because the data follow an exponential relationship, a plot of  $\log(y)$  versus time takes the form of a straight line, which allows the standard error ( $\varepsilon$ ) of the predicted value of  $\log(y)$  to be obtained. The 95% prediction limit (for  $\log(y)$ ) is given as  $\pm 1.96 \cdot \varepsilon$ ; the corresponding limit is for  $y$  is then given by  $10^{\pm 1.96 \cdot \varepsilon}$ .

However, while Romanoff found that, in general, all ferrous material alloys behaved similarly in the same soil, some low alloy steels did show variable performances in specific soil types. Generally steels with chrome content of  $\sim 5\%$  (with or without molybdenum, at  $\sim 0.5\%$ ) exhibited corrosion rates (weight loss or pitting) of about half of that plain low alloy/low carbon steels, except in very poorly aerated conditions, where they exhibited greater pitting, as shown in **Figure 7** (steels *D*, *E*, and *H*).

In the presence of high SRB activity, see **Section 2.19.2.6**, special considerations apply and localized, shallow pitting corrosion may be much higher than would otherwise be expected. In some instances, cast

**Figure 6** Comparison of measured metal loss for a range of steels in different soil types (clay and sand). Reproduced from Romanoff, M. *Underground Corrosion*; National Bureau of Standards, Circular 579 (April 1957). [Republished by NACE International, Houston, Texas, USA, 1989 ISBN 0-915567-47-4].

**Figure 7** Relative performance of different low alloy steels in different soil types. Reproduced from Romanoff, M. *Underground Corrosion*; National Bureau of Standards, Circular 579 (April 1957). [Republished by NACE International, Houston, Texas, USA, 1989 ISBN 0-915567-47-4].

iron pipes of 8mm thickness have become perforated within a year under such conditions, while perforation rates of 1–2 mm year<sup>-1</sup> at ambient temperature are not uncommon. Under anaerobic/aerobic cycling conditions, where SRB mediated sulfide corrosion may be exacerbated by the production of elemental sulfur, and/or at elevated temperatures corrosion rates of 3–5 mm year<sup>-1</sup> may be encountered.

### 2.19.3.2 Other Metals and Alloys

Romanoff obtained only limited experimental data for stainless steels in soils, as summarized in Table 1, which shows improved performance with regards to both general metal loss and pitting except for ferritic steels (grade UNS S41000/EN 1.4006 and UNS S43000/EN 1.4016), which were still relatively high at 0.75 and 0.31 mm year<sup>-1</sup>, respectively.

**Table 1** Corrosion performance of some stainless steels

Stainless steel grade		General metal loss ( $\mu\text{m year}$ )	Pitting rate ( $\mu\text{m year}$ )
UNS system	EN system		
S41000	1.4006	750 $\pm$ 650	68 $\pm$ 44

Source: Modified from Romanoff, M. *Underground Corrosion*; National Bureau of Standards, Circular 579 (April 1957); [Republished by NACE International, Houston, Texas, USA, 1989 ISBN 0-915567-47-4].

Since the work carried out by Romanoff, a wider range of stainless steels are now available for pipework, tanks, and anchorage systems. Typically, the higher the pitting resistance equivalent number (PREN) the better the corrosion resistance for stainless steels in soils and with the main factor being consideration of chloride content and resistivity, SRB can also attack stainless steels.<sup>12</sup>

The corrosion behaviors of other metals, including copper, lead, and zinc obtained by Romanoff<sup>2</sup> are summarized in Figure 8 for exposure in a combination of several different soil types and for tidal marsh, clay, and sandy loam.

### 2.19.3.3 Influence of Soil Parameters on Corrosion Rate

Romanoff concluded that the main parameter that influenced the corrosion rate of ferrous materials was the extent of aeration, with the highest corrosion rates occurring in soils with poor or very poor aeration (poor or very poor drainage) compared to lower corrosion in soils possessing good aeration (good drainage). Pooled data for steel samples from 47 test sites<sup>2</sup> grouped by degree of aeration as defined by Romanoff are shown in Figure 9. However, it is clear that aeration alone is insufficient to account for the variability among different soils.

The same pooled data from Romanoff, if grouped by resistivity, soil type, pH, or salt content, show similar levels of correlation. Consequently, these factors have been incorporated into the development of various methods for assessing corrosivity, as described later.

**Figure 8** Average metal loss rate ( $\text{g m}^{-2} \text{ day}^{-1}$ ) and maximum pit depth (normalized to 12 years exposure) for iron, steel, copper, lead and zinc. Reproduced from Romanoff, M. *Underground Corrosion*; National Bureau of Standards, Circular 579 (April 1957). [Republished by NACE International, Houston, Texas, USA, 1989 ISBN 0-915567-47-4].

#### 2.19.3.4 Long-Term Corrosion Rates in the Soil Environment

For most engineering applications, the rate of deterioration is considered over periods ranging from 20 to 100 years; however, corrosion in soils is a rare instance where exposure periods of more than 1000 years may also be relevant, both for strategic storage facilities (nuclear fuel storage, national archives, etc.) and with regard to archaeological artifacts.

In fact, ancient historical periods are defined by the metallurgy that was available at the time, from the Copper Age (4000–3500 BC), various Bronze Ages (Early 3500–2000 BC, Middle 2000–1600 BC, and Late 1600–1100 BC), and Iron Age (from 1100 BC to 500 AD). Lead was also widely used from 3000 BC onward. The different natural corrosion rates for the various metals and alloys, together with the soil conditions in which the metallic items were left, lead to a wide variation in the quantity and condition of artifacts found in archaeological sites, with some older artifacts fabricated from bronze being preserved in better condition than newer iron artifacts.

Studies over recent years have examined the impact of different soil parameters on bronze artifacts<sup>13</sup> and have shown that aeration and pH are the main factors, with highly aerated and/or acidic soils leading to the most severe deterioration, while low aeration (i.e., clay soils) leads to best preservation. These findings have wider implications as environmental changes, and in particular impact of acid rain on soils, could lead to deterioration of artifacts that

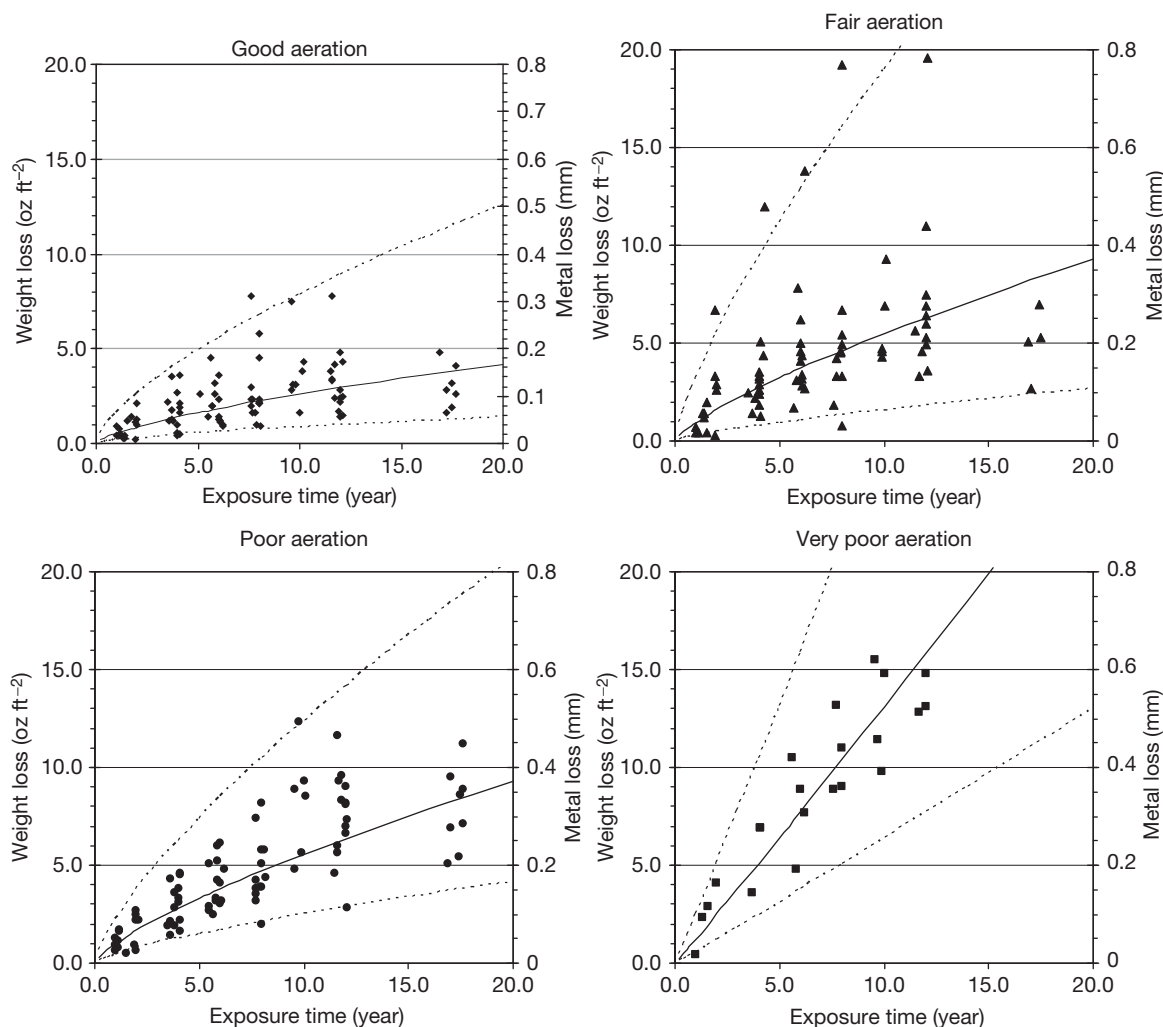

have been reasonably preserved for thousands of years but are located in soils of poor buffering capacity.

For iron artifacts, while acidic conditions will also lead to severe attack, poorly aerated/clay soils tend to lead to the converse condition,<sup>14</sup> which is consistent with the experience on modern ferrous materials as described above. Another factor that is important is the presence of soot in the soil, formed for example, from a funeral pyre or from destruction of a dwelling by fire, which can also lead to more extensive corrosion of the artifact.

#### 2.19.3.5 Disturbed and Undisturbed Soils

One of the main factors relating to corrosion rate in soils is whether the component is placed in disturbed or undisturbed condition. Disturbed soil is defined as one that has been mechanically moved and replaced (e.g., backfill used in laying a pipeline, burying a tank, etc.), whereas in the case of undisturbed soils the component has been driven directly into soil, for example, driven sheet steel piles, H-piles, tubular steel piles, or soil nails.

The process of mechanically moving the soil affects it by breaking up the soil (which can affect the cohesiveness of the soil) and also aerates the soil. Conversely, for driven components, the mechanical property and cohesive form of the soil are unaffected. Separate work by Romanoff in the 1960s<sup>3</sup> found that a soil which, if disturbed, would be considered corrosive, resulted in negligible corrosion if undisturbed.

**Figure 9** Pooled weight loss data for Bessemer steel (3" Pipe) from 47 different test sites, group by degree of aeration. Reproduced from Romanoff, M. *Underground Corrosion*; National Bureau of Standards, Circular 579 (April 1957). [Republished by NACE International, Houston, Texas, USA, 1989 ISBN 0-915567-47-4] – with regression lines and 95% prediction limits.

This work combined specific field trials plus observations of steel piling that were removed after 50 years exposure.

In many cases, the extent of metal loss was minimal and only limited isolated pitting observed, which for most types of piling is not structurally significant. In some cases, it was reported that the original mill scale was still intact when the pile was removed.

Examination of piling removed from permafrost<sup>15</sup> also showed that no corrosion occurred on the section of pile that was permanently in frozen conditions, with little corrosion occurring in the area above the frozen ground.

A survey carried out in 2000<sup>4</sup> confirmed Romanoff's overall findings relating to steel piling for most soils. However, cases of significant corrosion of steel piling (single side metal loss rates of  $0.06\text{--}0.11\text{ mm year}^{-1}$ ) were found where the ground was either contaminated by cinders/coal, or had low resistivity ( $<20\ \Omega\text{ m}$ ) or where acidic ( $\text{pH} < 4$ ) conditions occurred. In particular, this study identified problems at the interface between disturbed and nondisturbed areas, where differential concentration cells (macro-cells) are formed, as described above and as shown in [Figure 10](#). Here the corrosion is concentrated on the section of pile in the nondisturbed soil at the interface.

**Figure 10** Creation of differential concentration (differential aeration) cells between disturbed and nondisturbed soils. NACE Technical report 05101 *State-of-the-Art Survey on corrosion of steel piling in soils* (Dec-2001); published by NACE International (item no 24216); Houston, TX, USA.

## 2.19.4 Corrosivity (Aggressivity) Assessment

### 2.19.4.1 General

Various different methods for assessing the likely corrosivity of soils have been developed. In most cases, the different procedures assign ratings (values) to the various influencing factors and the sum of the ratings is used to assess aggressiveness. Schemes have also been proposed that incorporate a statistical approach, whilst others provide general guidance based on generic conditions or rely on direct measurement of corrosion rate in the soil.

The methodology used most extensively in the UK and Europe is on the basis of original work carried out in Germany<sup>9</sup> and first published in English in Beakman and Swenk.<sup>16</sup> In Germany, the system has evolved into DIN 50 929 Part 3.<sup>17</sup> The Eyre & Lewis system,<sup>18</sup> which is a derivative of the original German system, has been adopted by the UK Highways Authority for assessment of new bridge and road projects.

### 2.19.4.2 Resistivity

The simplest method of assessing soil corrosivity is solely on the basis of resistivity measurements. There

**Table 2** Assessment of soil corrosivity based on soil resistivity

Soil resistivity ( $\Omega m$ )	Corrosivity rating
>200	Essentially noncorrosive
100–200	Mildly corrosive
50–100	Moderately corrosive
30–50	Corrosive
10–30	Highly corrosive
<10	Extremely corrosive

Source: Reproduced from NACE Resource Centre (<http://events.nace.org/library/corrosion/SoilCorrosion/Severity.asp>).

are several different resistivity criteria; the most widely used method is summarized in **Table 2**.

Sandy soils are high up on the resistivity scale and therefore considered the least corrosive on the basis of this simplistic criterion. Clay soils, especially those contaminated with saline water, are at the opposite end of the spectrum. The soil resistivity parameter is widely used in practice and generally considered to be the dominant variable in the absence of microbial activity. However, it is widely acknowledged that resistivity alone does not determine overall soil corrosivity and hence most systems include assessment of other parameters.

### 2.19.4.3 Influence of SRB

A large scale study of many factors at 59 sites in the United Kingdom<sup>6</sup> lead to the finding that aggressive sites were characterized by soil resistivity of less than  $20 \Omega m$  or a mean redox potential more negative than +400 mV (the redox potential is defined as the potential difference measured between a platinum electrode and a suitable reference electrode in contact with the soil, normalized to standard hydrogen potential (SHE) and a pH of 7<sup>19</sup>). Low redox potential is attributed to reduced sulfur compounds, particularly sulfides, produced by the activities of SRB. 'Borderline' cases were classified according to water content – those containing more than 20% water being deemed aggressive soils. Similarly, all soils with a mean soluble iron content of over  $120 \text{ mg kg}^{-1}$  were found to be aggressive.

It is the authors' experience that, in addition to redox measurements (which should, be performed on undisturbed soil *in situ*), it is also useful to test small samples of soil for the direct presence of SRB. A pragmatic procedure, developed by the authors, involves two different sized samples inoculated (in triplicate) into vials of SRB culture medium

(see Chapter 2.20, Corrosion in Microbial Environments), which are then immediately resealed. One set of samples (milli-sample) would comprise 100–200 mg of soil material, the other set (micro-sample) less than 10 mg of material (i.e., literally only a few grains). If, after 14 days incubation at  $\sim 30^\circ\text{C}$ , all the milli- and micro-sample test vials turn black, the soil is designated as moderate to severely infected with SRB, and likely to present a high threat of MIC. If the micro-samples only turn black, the soil may be designated as low to moderately infected with SRB and hence, as a lower threat of MIC.

#### 2.19.4.4 DIN 50 929 Part 3 Criteria

DIN 50 929 Part 3<sup>17</sup> provides by far the most comprehensive methodology and has been validated on many different projects, following comparison of predicted metal loss to actual metal loss.

In DIN 50 929 Part 3, the aggressiveness of soil is determined by consideration of soil type, extent of contamination, resistivity, pH, moisture content, soil condition (i.e., disturbed/undisturbed), total alkalinity/acidity (buffer capacity), combined chloride/sulfate content (aqueous extract), sulfate content (acid extract), sulfide content, presence of ground water, vertical/horizontal homogeneity, and external stray current.

DIN 52 929 Part 3 also assesses ground water in a similar manner to soil by considering water mobility, position (fully submerged, at water/air interface or in splash zone), chloride and sulfate content, buffer capacity, calcium content, pH, and external stray current.

The individual parameters are assigned values ranging from +4 (nonaggressive) to –12 (strongly aggressive), on the basis of defined criteria. The sum of the various items can range from a best case of +4 to a worst case of –47, and from this the overall corrosivity (aggressivity) is assessed. This also allows an estimate of the expected corrosion rate and the practical range (essentially a factor of  $\times 2$  on the median corrosion rate), as shown in Table 3.

#### 2.19.4.5 Eyre and Lewis System

The Eyre and Lewis system<sup>18</sup> is a development of the original German assessment method<sup>9</sup> and has been adopted by the UK Highway Agency<sup>20</sup> for determining corrosion protection requirements for all highway structures.

The main differences between the two systems is that the Eyre and Lewis system of assessment includes the redox potential of the soil and assesses the buffering capacity (i.e., the extent to which the pH could change if acid or alkali is added) by measuring the bicarbonate content of soil as opposed to the analysis required in DIN 50 929 part 3.

#### 2.19.4.6 AWWA/DIPRA

DIPRA (Ductile Iron Pipe Research Association, formally CIPRA – Cast Iron Pipe Research Association) developed a classification for assessing soils for determining whether protective measures are required for ductile iron pipes for use in water and waste water applications, which was first published in 1968.<sup>21</sup> This method was adopted by AWWA (American Water Works Association) and is now more commonly referred to as the ‘AWWA 10-point system.’<sup>22</sup> It is used widely in North America, where it defines whether or not the minimal level of protection as required by AWWA, that is either no protection or application of plastic liner, for cast iron water and sewer pipes. It has also been adopted as part of other assessment schemes.<sup>7</sup>

The system assigns scores dependent on resistivity, pH, redox, sulfides, and moisture content, with a total score greater than 10 considered corrosive and requiring application of plastic liner. While it would appear to be similar to other systems as described above,<sup>9,17,18</sup> and there is evidence of good correlation between the predicted score and actual performance,<sup>5</sup> there is also evidence that it can underestimate the soil corrosivity.<sup>23,24</sup> This is on the basis of the observed corrosion performance being at

**Table 3** Assignment of aggressiveness and expected corrosion rates for soils

Sum of ratings	Aggressiveness	General corrosion rate ( $\text{mm year}^{-1}$ )	Localized attack ( $\text{mm year}^{-1}$ )
$\geq 0$	Ia Virtually nonaggressive	0.005 (range 0.0025–0.01)	0.03 (range 0.015–0.06)
–1 to –4	Ib Weakly aggressive	0.01 (range 0.005–0.02)	0.05 (range 0.025–0.1)
–5 to –10	II Aggressive	0.02 (range 0.01–0.04)	0.2 (range 0.1–0.4)
$< -10$	III Strongly aggressive	0.06 (range 0.03–0.12)	0.4 (range 0.2–0.8)

Source: Reproduced from DIN 50 929 Part 3. Probability of Corrosion of Metallic Materials when Subject to Corrosion from the Outside. Buried and Underwater Pipelines and Structural Components, Sep-1985.

variance to the predicted corrosion condition. Similar variances between predicted corrosivity by the DIPRA method and actual experience, where other systems (e.g., DIN 50 929 part 3) showed good correlation, have also been observed by the authors. This is, in part, because most assessments only take into account the point scores, while the full procedure (as detailed in AWWA C105) actually requires the soil type to be taken into consideration as well. It is this omission that, in the authors' opinion, is one of the reasons for the variable results of the system.

DIPRA has recognized the limitations in its original system and published an extended methodology in 2004, referred to as Design Decision Model™ (or DDM™).<sup>23,24</sup> This extends the general hazard assessment to include the effect of chlorides, bimetallic effects, and known corrosive environments (i.e., soil type) and also now includes a risk assessment as shown in **Figure 11** (i.e., considering the combination of both likelihood of failure and consequence of failure, used in corrosion risk assessments as described in other chapters of this publication).

As the risk of corrosion increases the required level of protection (as outlined in **Section 2.19.6** below) is then increased, as follows:

1. Negligible – install the pipe as-manufactured with its protective standard shop coating/annealing oxide system.

**Figure 11** Design decision method (DDM™) corrosion risk assessment. Reproduced from Kroon, D. H.; Lindermuth, D. L. *Corrosion Protection of Ductile Iron Pipe*, Paper no 04046, NACE Corrosion 2003, New Orleans, March 2004; NACE International; Houston, Texas.

2. Low – encase the pipe in polyethylene.
3. Medium – encase the pipe in polyethylene or encase the pipe and provide bonded joints.
4. High – encase the pipe in polyethylene and provide bonded joints or provide life-extension cathodic protection currents, with or without encasement.
5. Severe – apply cathodic protection.

#### 2.19.4.7 Mean Time Before Failure (MTBF)

As noted previously, there has been increasing concern relating to environmental contamination due to leaking underground storage tanks caused by corrosion, especially in North America. This led to the development of ASTM standard G 158<sup>25</sup> for assessing the condition of buried tanks and applying remedial measures to ensure integrity, which is now mandated in the United States.

One of the methods described in the standard is the so called MTBF method, which determines the likely time to failure (through wall pitting in this case) of buried storage tanks, on the basis of a statistical assessment of various soil parameters and was developed from previous published work.<sup>26</sup> The parameters used in the assessment are obtained either directly on site or from samples analyzed in a laboratory and compared to a data set of corrosion rates obtained from a number of other sites, so as to be able to demonstrate a statistical confidence level of 99%.

The standard indicates that a multivariate nonlinear regression analysis that contains the following minimum essential variables may be used, for example, as shown in **eqn [2]**:

$$E(\text{age}) = f(R, M, Cl, pH, S, SC, TS, P) \quad [2]$$

where  $E(\text{age})$  = unconditional predicated age to corrosion failure;  $R$  = resistivity;  $M$  = moisture content;  $Cl$  = chloride ion content;  $pH$  = soil pH;  $S$  = sulfide content;  $SC$  = stray current magnitude;  $TS$  = tank size; and  $P$  = tank structure-to-soil potential.

However, the standard also allows other parameters such as redox potential, sulfate content and others tests as may be considered appropriate to be included.

It is clear that while the overall procedure as described in ASTM G 158 is generally sound, it first requires the user to develop a sufficiently large data set of soil types, environmental conditions, and associated measured corrosion rates of actual structures before any assessment for further tanks can be carried out. Several commercial organizations have

developed data sets and are therefore able to carry out such assessments. The requirement for a 99% confidence level would normally be sufficient to compensate for any limitation of data for a particular parameter. In the absence of a specific database to allow an assessment, the extensive data from the original work by Romanoff<sup>2</sup> could be utilized.

Other statistical approaches to the development of predicting corrosion rates and time to failure have also been proposed by other workers.<sup>27,28</sup>

#### 2.19.4.8 Direct Measurement Approach

As an alternative (or in support of) assessment of soil corrosivity by consideration of relevant parameters, several workers have carried out direct measurement of corrosion in soils, either in the field or on soil samples brought back to the laboratory. Such measurements have used a wide range of different procedures including, for example, corrosion coupons, linear polarization resistance (LPR), electrical resistance (ER), and other electrochemical techniques.

As would by now be realized the most extensive use of exposure coupons to date was carried out by Romanoff,<sup>2,3</sup> who also described some of the earliest electrochemical measurements using what was essentially a LPR measurement, which was reported as giving very good correlation to weight loss measurements.

More recently, the use of ER and LPR probes has been applied to corrosion testing in soils, either directly<sup>29,30</sup> or as part of assessing performance of cathodic protection systems.<sup>31,32</sup>

In any system using buried probes, it should be self-evident that for meaningful information to be obtained the probes must be buried in the same soil and under the same conditions as the structure (pipeline/foundation) they are intended to represent; this is particularly important if they are being used to assess corrosivity for driven components (such as soil nails, driven piles, etc.). It should also be self-evident that an isolated probe/exposure coupon will provide only information on the inherent corrosivity of the soil. If there is a concern relating to either long-line (macro-cell) corrosion or external stray current corrosion, the probe must be electrically connected to the structure of concern. However, there must also be a method of temporarily disconnecting the probe from the structure<sup>31</sup> to allow measurements to take place (when using ER probes) or some other means of isolation (when using LPR probes).

#### 2.19.4.9 Summary

The key features associated with any of the different methods of assessment as applied to soils are the following:

- All soils contaminated with coal, coke, industrial waste, and so on are strongly aggressive.
- The lower the resistivity the more aggressive the conditions, with very low resistivity soil ( $<10 \Omega \text{ m}$ ) normally associated with strongly aggressive conditions.
- While soil/groundwater pH can range from  $<4.5$  to  $>9.5$ , its effect can be less important than the buffering capacity of the soil. Soils which are strongly alkaline buffered (measured as alkalinity to  $K_{S\ 4.3}$  of  $>1000 \text{ mmol kg}^{-1}$  or carbonate content  $>1500 \text{ mmol kg}^{-1}$ ) have sufficient residual alkalinity to be beneficial. Soils which are strongly acidic buffered (as measured by acidity to  $K_{B\ 7.0} > 20 \text{ mmol kg}^{-1}$ ) are very corrosive, while a low buffering capacity (e.g.,  $K_{B\ 7.0} < 5 \text{ mmol kg}^{-1}$ ) has little impact on overall aggressiveness.
- Where a metal component passes through different soils (e.g., a pipeline running from one soil to another or a pile/anchorage driven vertically through different soil layers) the main concern relates to the formation of differential aeration and/or concentration cells, where corrosion will be located at or just below the interfacial layer.
- Buried structures are also at risk from stray current sources (e.g., from neighboring cathodic protection systems, dc welding, dc railway systems, etc.). This risk is assessed by the change in potential on site and hence measurements of structure-to-soil potential (as required in DIN 50 929 part 3 and others systems) are only directly applicable to existing facilities. Other methods are available to assess stray current risks on site or during the design stage, using computer modeling.<sup>33</sup>
- Where the soil contains active SRB, which can be determined by the presence of sulfides, measurement on site of redox potential or bacterial assay, it can lead to microbiologically influenced corrosion (MIC) which can be severe.

It should also be noted that while some assessment methods (in particular DIN 50 929 Part 3) state that they cover both disturbed and undisturbed soil conditions, in practice the rate of corrosion of components in undisturbed soil is significantly lower. As noted previously, Romanoff<sup>3</sup> concluded that for driven piles the

portion in the undisturbed soil did not suffer significant attack. This concept has been adopted in the recent Eurocode 3 Part 5<sup>34</sup> where projected corrosion rates for a particular soil show essentially a doubling of corrosion rate depending on whether the soil conditions are compacted, driven or noncompacted.

In the case of ground anchorages,<sup>35</sup> the appropriate method of determining aggressiveness will be dependent on the type of anchor. For high strength prestressed ground anchors, the aggressiveness of soils (disturbed or undisturbed) is directly relevant, for example, in ground anchorage systems where the steel component is in direct contact with the soil (e.g., where the tendon has lost its cement grout cover) or the protective system fails (e.g., tie bars with damaged protective tape wrapping). For other anchor types, for example, soil nails or drilled piles, the steel component is inserted into undisturbed soil. For permanent anchorages, where the components are protected by a corrosion protection system, in accordance with most national standards, the steel tendon is not in direct contact with the ground; hence, it is the aggressiveness of the ground water that is most relevant, as it is the ingress of ground water through any breaks in the protective system that is of concern.

There are also many more published soil corrosivity assessment methods than just those described here, with varying degrees of acceptance and success.

Where stainless steels are being considered, their use should be on the basis of chloride content and soil resistivity. In the absence of external stray currents and for soils with groundwater pH > 4.5, suitable stainless steel grades that can be used without coatings or cathodic protection are shown in **Table 4**.

**Table 4** Use of stainless steels in soils

## 2.19.5 Metallic Coatings in Soils

Several different metallic coatings have been used to provide protection to ferrous components in soils, principally galvanizing but also thermal spray coatings of zinc, aluminum, and zinc–aluminum alloys.

The performance of zinc coatings is interesting in that the mechanism of protection in soils differs from that provided in other environments (in particular natural waters and the atmosphere). In soils, initially the zinc acts as a barrier with a generally lower natural corrosion rate (compared to iron or steel) and also provides galvanic protection at any damage site where substrate is exposed. However, the longer term protection from the zinc coating is also provided by the *de facto* formation of insoluble corrosion product comprising zinc salts (mainly sulfates and carbonates), which forms as a semi protective film *in situ*. This extends the level of protection, even when the bulk of the zinc has been consumed.<sup>36</sup>

The overall corrosion rate of zinc is dependent on soil pH and resistivity, the performance of the metal being less efficient in acidic soils. The method for determining the rate of deterioration of zinc in galvanized steel sheets used, for example for culverts, was developed by California Division of Highways<sup>37</sup> (based on the work by Romanoff), as shown in **Figure 12**. Note 16 Gage galvanized steel sheet is nominally 0.06 inch (1.5 mm) thick with 3.5 mil (88 μm) thick zinc coating. Gage 14, 12, 10, and 8 galvanized sheets are respectively 0.075, 0.105, 0.135, and 0.165 inch (1.9, 2.7, 3.4, and 4.2 mm) all with nominal 3.5 mil (88 μm) zinc coating.

Aluminum coatings act only as a barrier, with no significant long term protection once the aluminum has been consumed (which can occur rapidly in alkaline soils).

The use of thermal spray zinc–aluminum alloy, in particular Zn85–Al15, has been shown to provide improved performance, compared to pure zinc coatings, in many soil environments, particularly when used with a finishing layer (typically an thin, semiporous, epoxy coating). The research indicates that the presence of the aluminum reduces the self corrosion of the coating, while still allowing the formation of *in situ* insoluble zinc salts. In fact, by slowing the rate of formation of the zinc salts the protective nature of the film is improved.<sup>38,39</sup> This allows a zinc/aluminum coating to be used in an extended range of soil types compared to a zinc

**Figure 12** Estimating service life of galvanized steel in soils. Reproduced from *NACE Corrosion Engineers Reference Book*, 3rd ed.; Baboian, R. Ed., ISBN 1-57590-127-7.

coating. However, it is not suitable for very aggressive soils, for example, acidic peaty soils ( $\text{pH} < 5$ ), polluted/contaminated soils (with cinders, slag, etc.), or marine soils below the water table (with resistivity  $< 5 \Omega \text{ m}$ ).

### 2.19.6 Corrosion Control Options

Practical corrosion control options for buried components are dependent on the structure/component type, soil environment, and impact of any resultant corrosion, and will normally comprise one or more of the following:

- do nothing
- application of a corrosion allowance
- use of selected backfill
- use of protective sheeting (for ductile iron pipe)
- application of organic protective coating (bitumen, epoxy, polyurethane, etc.)
- application of metallic coating (galvanizing, flame sprayed zinc/aluminum alloy)
- cathodic protection (galvanic or impressed current).

As can be seen, the option of do-nothing and/or inclusion of a corrosion allowance can be a practical consideration for some structures/components, where the soil aggressivity may be classed as negligible or low

(i.e., general metal loss rates of  $< 0.01 \text{ mm year}^{-1}$  or localized pitting rates of  $< 0.05 \text{ mm year}^{-1}$ ) and where the consequence of any corrosion is acceptable.

The use of a corrosion allowance is normally applied to piles where protective coatings are not suitable (see below). The corrosion allowance is an additional thickness over that necessary for structural strength to allow for metal loss over the design life (as detailed in the new Eurocode 3<sup>34</sup>).

The use of selective backfill, for pipelines or buried tanks, is another method of reducing the corrosion threat for buried components. Any backfill should be sifted to remove stones, which could damage the protective coating. Where the local soil is aggressive, for example, clay based, contaminated with cinders, low pH, or high salt content, imported material should always be used, although it has to be recognized that this is not always practical in remote sites. When selected backfill is used it is also important to ensure that the same material is applied across all components. This is because if backfills of significantly different compositions are used in different locations long-line (macro-cell) corrosion could develop. For example, in 1980 in Ortuella, near Bilbao, Spain, a butane gas tank, which was buried in predominantly limestone fill and connected to a poorly protected small bore pipe, was buried in nonselective backfill. This led to severe corrosion of the pipe causing a leak. This in turn resulted in an explosion in a school

basement and the deaths of forty-seven children and three adults.

Protective plastic sheeting has been used extensively for ductile iron pipes and, where the soil is moderately aggressive, it can provide benefit. It should be noted however, that there is a major variance between European and North American practice; in Europe plastic sheeting is applied over galvanized or thermally sprayed zinc coating plus bitumen, while in North America it has been applied over otherwise uncoated pipe.<sup>40</sup>

Protective coatings are widely applied as the principle method of corrosion control for buried components especially pipelines and buried tanks. They can also be applied to driven components (sheet steel piles, H-piles, soil nails, etc.); however, because the driving process is likely to cause significant mechanical damage to any applied coating, it cannot, in such circumstances, be considered as a primary protection measure. Nonetheless, the use of protective coating can still be beneficial, especially where cathodic protection will also be applied, as it will significantly reduce the current demand. There are a wide range of protective coatings that can be used for buried components (especially pipelines). These include tape wrap systems, bitumen, liquid applied epoxies and polyurethanes, fusion bonded epoxy, and multilayer epoxy/polyurethane coatings. Selection of an appropriate coating depends on the specific soil condition (in particular, whether the component will be below or above the water table). Mechanical damage of coatings from the soil (so called soil stress) can also be a major concern, especially for tape wrap and some epoxy systems).

For small components and cast iron, increasing use is made of metallic coatings (as summarized in Section 2.19.5) comprising galvanizing and flame sprayed zinc or zinc–aluminum alloys. However, it should be recognized that metallic coatings are more sensitive to soil pH than organic coatings; in particular, zinc coatings are not suitable for soils with  $\text{pH} < 5$  and aluminum coatings are unsuitable for  $\text{pH} > 9$ .

Successful cathodic protection can be defined as where the effective corrosion rate is  $< 0.01 \text{ mm year}^{-1}$ ; consequently use of cathodic protection may not be considered necessary for soils which are classed as ‘noncorrosive.’ However, for high risk assets (e.g., high pressure oil and gas pipelines, buried hydrocarbon storage tanks, etc.) with unacceptable consequences of failure, cathodic protection is almost universally applied, even in areas where soil aggressivity is negligible; its application to other assets is variable across the world. In some areas, in particular

in the tropics, the Middle East, North Africa and elsewhere, cathodic protection is applied to the majority (if not all) of buried facilities, for the simple reason that soils in these areas are often very aggressive.

Cathodic protection can be applied by either galvanic or impressed current systems, the decision being dependent on ground resistivity (zinc galvanic anodes are normally only used in soils with resistivity  $< 30 \Omega \text{ m}$ ; magnesium anodes  $< 150 \Omega \text{ m}$  and impressed current otherwise); but selection of the most appropriate system will be influenced by the availability of power supplies, access (for maintenance), required design life, and whether there are any concerns relating to over protection (which can lead to stress corrosion cracking).

## Glossary

**Anaerobic** In the absence of oxygen, cf. aerobic.

**Autotroph** An organism that produces complex organic compounds from inorganic carbon dioxide and an external source of energy, such as sunlight or chemical reactions of inorganic compounds. All green plants and certain specialized bacteria are autotrophs.

**Bacteria** Unicellular microorganisms, typically a few micrometers in length and having many shapes, including spheres, rods, and spirals.

**Biocide** Usually refers to a chemical agent that is intended to kill microbiological life, as distinct from sterilization by heat or radiation.

**Biofilm** A complex aggregation of microorganisms marked by the excretion of a protective and adhesive matrix and also often characterized by surface attachment, structural heterogeneity, genetic diversity, and complex community interactions.

**Biogenic** Arising from living processes.

**Biostud** One of a set of small, replaceable metal coupons mounted inside a side stream, used to monitor biofilm.

**Chlorination** The process of adding elemental chlorine, hypochlorous acid, or hypochlorite ions in solution to water as a biocide to reduce the prevalence of microorganisms.

**Fungi** Microorganisms with cells much larger than bacteria that digest their food externally, absorbing nutrient molecules into their cells. They were originally classified as simple plants; however, they have been separated as heterotrophs.

**Heterotroph** An organism that requires organic substrates to get its carbon for growth and development in contrast with autotrophs, which use inorganic carbon dioxide as their sole carbon source. All animals are heterotrophic, as well as fungi and many but not all bacteria.

**Mesophilic** Microorganisms that grow optimally within the temperature range 20–40 °C.

**Metabolism** The complete set of chemical reactions that occurs in living cells. These processes are the basis of life, allowing cells to grow and reproduce, maintain their structures, and respond to their environments.

**Microbially-influenced corrosion (MIC)** The deterioration of the essential properties of a

material due to reactions caused or promoted by the activity of microorganisms.

**Microorganism** Or *microbe* is an organism that is microscopic (too small to be seen by the human eye). The study of microorganisms is called microbiology. Microorganisms can be bacteria, fungi, archaea, or protists, but not viruses and prions, which are generally classified as nonliving.

**mg l<sup>-1</sup>** A concentration term to define the amount of a substance which is the practical numerical equivalent to the derived SI unit of milligrams per cubic decimeter (mg dm<sup>-3</sup>).

**Nitrate-reducing bacteria (NRB)** Nitrate-reducing bacteria, comprising many groups of bacteria that use nitrate as an oxidizing agent for their energy-generating metabolism, reducing it to nitrogen gas, sometimes with the generation of nitrite or other nitrogen oxides as by-products.

**Planktonic** Bacteria that are suspended or free floating in a liquid environment.

**Redox** Reduction/oxidation potential. High redox potentials ( $E_h$  positive) reflect oxidizing conditions, whereas low redox potentials ( $E_h$  negative) reflect reducing conditions.

**Sessile** Stationary bacteria that are permanently attached to a surface as a biofilm.

**Side stream** A small test pipe, generally equipped with a series of isolation valves, through which water flows and designed to hold multiple flush mounted, replaceable metal studs for the measurement, analysis, or testing of biofilms in industrial water systems.

**Souring** The appearance of hydrogen sulfide (H<sub>2</sub>S) in production fluids as a consequence of the introduction and activity of sulfate-reducing bacteria, which generate H<sub>2</sub>S within a waterflooded zone of (particularly) a subsurface petroleum reservoir.

**Sulfate-reducing bacteria (SRB)** Sulfate-reducing bacteria, comprising several groups of anaerobic bacteria that use sulfate as an oxidizing agent for their energy-generating metabolism, reducing it to sulfide, which appears as H<sub>2</sub>S, sulfide ions, metal sulfides, or a combination of these forms according to the conditions.

**Substrate** Any substance required for the growth or metabolism of a microorganism, other than materials required in trace quantities only.

**Thermophilic** Microorganisms that grow optimally at temperatures above the mesophilic range and most typically at greater than 55 °C.

**Water injection** A method used in crude oil production where water is injected back into the subsurface petroleum reservoir to increase pressure and thereby stimulate production.

### 2.20.1 Introduction

‘Microbiologically-induced corrosion,’ nowadays more commonly termed ‘microbially-influenced corrosion’ (MIC), is a rather special case of the widespread occurrence of biodeterioration of materials. It is important to recognize that MIC of metals is not fundamentally different from other types of aqueous electrochemical corrosion. Microorganisms do not directly consume metals in the way that they do various types of organic substances; it is rather that aggressive environments are created by certain types of microorganisms as by-products of their energy-obtaining metabolism.

Microorganisms can be viewed as ‘catalytic’ entities, bringing about chemical reactions that would otherwise not occur because of their high activation energy. Such processes may involve the production of aggressive chemical agents, such as acids, or the consumption of substances that are important in corrosion reactions, such as oxygen or nitrite corrosion inhibitors. Alternatively, the physical presence of microorganisms may form a slime or poultice, leading to differential aeration corrosion or crevice corrosion. Some microorganisms also chemically break down the desirable physical properties of lubricating oils and protective coatings.<sup>1–3</sup>

Microorganisms, including the corrosion-inducing microorganisms, are present almost everywhere in soils, freshwater, seawater, and air. Therefore, the mere presence of microorganisms in an environment does not necessarily indicate a corrosion problem. What is important is the number of microorganisms of the relevant types. The salient characteristics of these microorganisms from the engineer’s viewpoint are that they are small, ubiquitous, potentially very rapid-growing, and subject to certain common restraints such as temperature, pH, and nutrient availability. A corrosion problem exists only when conditions become favorable for a specific microbial population to ‘explode,’ giving rise to millions of cells per gram of environmental material. Even then, most microorganisms are harmless from the standpoint of corrosion;

therefore, it is important that microbiological assessment be type specific.

The role of microorganisms in the corrosion of metals was the subject of a number of classic review articles in the 1970s and 1980s<sup>4–7</sup>; though now somewhat dated, they are still worth reading for their clarity and objectivity. For more detailed recent reviews of the subject, the reader is referred to European Federation of Corrosion Report, number 29, published in 2000,<sup>8</sup> the ‘*Practical Manual on Microbiologically Influenced Corrosion*,’ published by NACE in 2001,<sup>9</sup> the very practical and engineering-orientated report titled ‘*Microbiologically Influenced Corrosion and Biofouling in Oilfield Equipment*,’<sup>10</sup> also published by NACE, and the ‘*Microbiologically Influenced Corrosion Handbook*’ published by the Industrial Press, USA.<sup>11</sup> For a detailed review of emerging tools and modern trends in MIC technology, the reader is referred to the research review article by Videla and Herrera.<sup>12</sup>

### 2.20.2 Microorganisms

#### 2.20.2.1 General

Microorganisms or ‘microbes’ are commonly defined as living entities that are too small to be visible to the human eye. The main differentiating feature, other than size alone, between microorganisms and larger, more complex organisms is that there is little or no degree of cell differentiation, one cell being able to emulate the functions of the whole organism. The microorganisms traditionally comprise bacteria, fungi, algae, and small unicellular animal-like protists, but not the minute and very simple (in biological terms) viruses and prions, which are now generally classified as ‘nonliving.’ Microorganisms are often described as single-celled (unicellular) organisms; however, some unicellular protists are visible to the human eye, and some multicellular species are microscopic. It seems to be a general biological principal that every criterion we devise for defining and classifying things breaks down at some point. We need to remember that classification – the process of putting objects into ‘pigeon holes’ – is something fundamental to human beings rather than nature. However, such classification is useful and necessary in reducing chaos to some semblance of order.

#### 2.20.2.2 Bacteria

The true bacteria are unicellular microorganisms, neither animals nor plants, but belonging to a separate and more primitive domain of organisms called

prokaryotes. They are a few micrometers in size and have many different shapes, including spheres, rods, and spirals. Though often occurring in pairs, clusters, or chains owing to incomplete separation after cell division, such aggregates are not essential to their existence. Bacteria are ubiquitous, living in almost every possible habitat on the planet, including soil, underwater, and even deep inside the earth's crust. Some types are aerobic, requiring oxygen, whereas other types are anaerobic, growing in the absence of oxygen.

The defining characteristic of bacterial cells, apart from their very small size, is that they do not contain a nucleus or other membrane-bound discrete structures having specialized functions (organelles). Bacteria are also far more metabolically varied than higher organisms, and the various diverse species are able to obtain energy by carrying out a wide range of chemical reactions. Most types of bacteria are heterotrophs, meaning that they do not fix their own carbon through photosynthesis, but use the oxidation of organic carbon fixed by other organisms. However, a few specialized bacteria carry out inorganic reactions involving oxidation or reduction of nitrogen, sulfur, or iron. It is the activities of these latter groups, the so-called chemolithotrophic bacteria, that most concern the corrosion engineer, even though they represent a tiny minority of the bacteria in the biosphere.

### 2.20.2.3 Fungi

Fungi were originally classified as plants; however, they have more recently been separated, as they are heterotrophs and are now thought to be more closely related to animals than to plants. The fungi are now placed in their own kingdom. Fungal cells are much larger than those of bacteria and always contain nuclei. The simplest fungi are yeasts, which are completely unicellular, as are bacteria, and reproduce by 'budding.' Most fungi are filamentous organisms, often referred to as moulds, comprising a tangled mass of filaments (hyphae), known collectively as a mycelium. The higher fungi include most common mushrooms, which are clearly large and multicellular, at least in one phase of their life cycle, but are biochemically and genetically closely related to the microscopic fungi. The fungi of most interest to the corrosion engineer are those that attack some types of polymers and paints and the 'kerosene fungus,' which secretes organic acids and is implicated in the corrosion of aircraft integral fuel tanks.

### 2.20.2.4 Algae

Algae are pigmented organisms (most commonly green, brown, or red) possessing the same photosynthetic mechanism as higher plants but having no true tissues, despite the enormous size of some marine algae (seaweeds). Their main interest to the engineer is the development of fouling masses in environments where light can penetrate, giving rise to microenvironments beneath which harmful bacteria may proliferate.

### 2.20.2.5 Biofilms

Though bacteria and other microorganisms can and do exist in the free floating state, they all have a propensity to attach to surfaces, where they proliferate, giving rise to slime and deposit formation. Microorganisms that float or swim in water are called *planktonic* bacteria. Microorganisms that attach to a substrate (e.g., metal) surface are called *sessile* bacteria. Biofilms comprise accumulations of living and dead microorganisms and their secretions together with entrained organic and inorganic debris. Microbial corrosion generally occurs beneath such biofilms. In addition to corrosion, biological fouling in industrial water systems can, for example, result in decreased efficiency of heat exchangers and plugging of tubes; slimes in cooling towers can cause rot of timber slats. Biofilm that detaches from surfaces can plug pumps and pipe work in cooling systems.

Most of the microorganisms present in industrial systems are present in biofilms and the most common types of biofilms are largely bacterial in nature. As noted earlier, various types of bacteria can grow with or without oxygen. Bacteria that need oxygen to grow are called *aerobes* or aerobic bacteria. Bacteria that need little or no oxygen to grow are called *anaerobes* or anaerobic bacteria. All these broad types of bacteria have a role in a typical biofilm. [Figure 1](#) shows the steps in biofilm.

Biofilm formation begins when (1) small amounts of organic material attach to the metal surface; (2) microbes then attach onto the organic layer; (3) a thick biofilm develops; (4) the biofilm becomes thick enough to exclude oxygen from the metal surface and forms an anaerobic zone near the surface; (5) aerobic and anaerobic bacterial species develop where conditions are most favorable for them; the biofilm thickens until parts of it are torn away by flowing water. The process begins again when the detached biofilm adsorbs onto another part of the

**Figure 1** Steps in biofilm formation.

**Figure 2** Dense biofilm on a metallic surface.

metal surface. The time required for this process is very much dependent on temperature and nutrient availability, but may be as short as 10–14 days under favorable conditions. The biofilm can thus provide very favorable conditions for both anaerobic and aerobic bacteria, growing in consort. Localized corrosion can develop on the metal surface and can cause corrosion pitting. An example of dense biofilm formation in an industrial water system is shown in [Figure 2](#).

Although it is true that corrosion-inducing microorganisms do not exist in isolation, but rather they form part of the complex microbiological consortia of biofilms, there has nevertheless been a tendency by recent reviewers to approach the subject of MIC from the point of view of the microbiologist rather than the engineer and to emphasise the complexity and diversity of such communities. It is not really necessary to either identify or to understand in detail these multifarious microbial populations in order to

comprehend the presence and activity of specific problem microbes.

### 2.20.3 Types of MIC

As emphasized in [Section 2.20.1](#), the immediate cause of corrosion is electrochemical in all cases we are about to consider. The ways in which metabolic activities of certain microorganisms are believed to bring about or contribute to electrochemical corrosion may be broadly categorized as follows:

- (a) Direct chemical action of metabolic products such as organic acids, sulfuric acid, or reduced sulfur compounds, especially sulfides or chelating agents.
- (b) Generation of an electrochemical cell by deposition of cathodic and conducting metal sulfides, often in conjunction with mechanism (a).
- (c) Cathodic depolarization by removal of hydrogen associated with anaerobic growth, frequently suggested to occur in conjunction with mechanisms (a) or (b) or both. This proposed mechanism is contentious and is now less widely believed than it formerly was.
- (d) Localized electrochemical effects because of changes in oxygen concentration, pH, etc., which establish local differential cells often in conjunction with mechanisms (a) and (b). The physical presence of the biomass in itself contributes to this mechanism.
- (e) Removal of inhibitory substances, most notably nitrite corrosion inhibitors but also possibly amines.

- (f) Direct degradation of protective coatings by utilization of one or more of their constituents as a source of carbon, thereby reducing the efficiency of the protective system.

The most important of these mechanisms will now be considered in turn, with brief reference to illustrative case histories and with a particular emphasis on the monitoring of trends and the identification of remedial measures.

## 2.20.4 Corrosion by the Sulfate-Reducing Bacteria

### 2.20.4.1 Situations Effected

The most important group of microorganisms associated with corrosion belongs to the rather diverse group of bacteria known as the sulfate-reducing bacteria (SRB); the vast majority of MIC failures are related to their activities.

SRB live in oxygen-free environments (i.e., SRB are anaerobic bacteria), where they obtain their required carbon from organic nutrients and their energy from the reduction of sulfate ions to sulfide. SRB will only flourish and cause damage if they can obtain sufficient sulfate, which is abundant in many freshwaters, seawater, and soils. Sulfide appears as dissolved or gaseous hydrogen sulfide ( $\text{H}_2\text{S}$ ),  $\text{HS}^-$  ions,  $\text{S}^{2-}$  ions or metal sulfides, or a combination of these according to conditions. Sulfides are highly corrosive to many metals. In the case of iron and mild steel, the characteristic black iron sulfide ( $\text{FeS}$ ) corrosion products liberate  $\text{H}_2\text{S}$  on acid treatment, distinguishing it from black iron oxide (magnetite). The corrosion products are often loose and when dislodged exhibit pits lined with bright metal corresponding to areas of anodic dissolution, but are sometimes also hard and adherent.

The most commonly encountered SRB type belongs to the genus *Desulfovibrio* (Figure 3). In natural conditions, SRB grow in association with other microorganisms and use a range of carboxylic acids and fatty acids, which are the common by-products of other microorganisms. They couple the oxidation of these carbon sources to sulfate reduction. For example:

Bacteria of this type can also use molecular hydrogen instead of organic carbon, to sulfate reduction:

**Figure 3** *Desulfovibrio*, a common genus of SRB as viewed under a phase contrast microscope. Bar = 10  $\mu\text{m}$  in length.

Conditions at the base of even thin biofilms can be ideal for growth of SRB, with high organic nutrient status, no oxygen, low oxidation–reduction (redox) potential, and protection from biocidal agents. SRB activity can thereby produce active sulfide-mediated corrosion even in systems where the bulk liquid phase has a low nutrient status, a high oxygen concentration, and will not support growth of anaerobic bacteria.

Most types of SRB will only grow in the pH range 5–10 and the temperature range 5–45  $^{\circ}\text{C}$ , up to a pressure limit of  $\sim 500$  atm,<sup>13</sup> although some less common groups of SRB have the ability to grow at elevated temperatures (thermophiles) up to at least 70  $^{\circ}\text{C}$ . The thermophiles are most commonly encountered in produced water from hot petroleum reservoirs; however, Postgate,<sup>14</sup> in his definitive monograph on the microbiology of the SRB, cites two cases of corrosion by thermophilic SRB activity, one case being in a tank of hot molasses at a sugar refinery, the second being a transformer tank buried in London clay, where the temperature was 60–80  $^{\circ}\text{C}$  for long periods.

The muddy bottoms of any relatively stagnant bodies of water with a high biological oxygen demand often support massive growth of SRB, as may waterlogged soils. Any metallic installations buried or immersed in such environments can be expected to suffer badly from SRB-mediated external MIC. The most serious economic problem is to pipelines, though sheet piles, hulls of ships, piers, etc., are also frequently attacked. In some instances, cast iron pipes of 0.25 in. thick have become perforated within a year under such conditions, while perforation rates 1–2 mm year<sup>-1</sup> at ambient temperature are not uncommon. Under anaerobic/aerobic cycling

conditions, where SRB-mediated sulfide corrosion may be exacerbated by the production of elemental sulfur, and/or at elevated temperatures, corrosion rates (CRs) of several millimeters per year may be encountered. This type of corrosion typically takes the form of shallow pitting attack, which may be either widespread or highly localized. A classic example of such morphology is shown in [Figure 4](#); this is a case of unprotected sheet steel piling attack in highly SRB-infested estuarine mud. The metal surface was grit blasted to remove the copious black iron sulfide corrosion product.

Oil field water handling systems, especially wet crude oil production pipelines and water injection pipe work, are beset by internal corrosion problems due to SRB-mediated internal MIC, most commonly at the bottom of line locations of water and particulate drop out. Low-velocity lines and storage tanks, aircraft jet fuel tanks and lines, hydrotest waters, cooling waters, and facilities handling wastewaters suffer similarly.

The petroleum production industry has been particularly plagued by the activities of SRB, because it handles large volumes of deaerated water. These waters can become very 'sour' with  $\text{H}_2\text{S}$  if infection with SRB occurs. The phenomenon of unexpected increase in  $\text{H}_2\text{S}$  concentrations in produced fluids from petroleum reservoirs (reservoir souring) has been observed over a period of many years in different areas of the world.<sup>15–18</sup> It is a very serious problem for that industry and considerable money has been invested in biocide-treatment programs for water injection, with the principal aim of killing or controlling this group of microorganisms. For a more

detailed modern appraisal of the problems of microbiological control in oilfield water systems, the reader is referred to the book by Davies and Scott.<sup>19</sup>

A large-scale study of external MIC of buried steel structures at 59 sites in the United Kingdom<sup>20,21</sup> lead to the suggestion that aggressive sites were characterized by soil resistivity of less than  $2000\ \Omega\text{ cm}$  or a mean redox potential more negative than  $+400\text{ mV}$  (on the hydrogen scale) at pH 7. Borderline cases were classified according to the water content – those containing more than 20% water being deemed aggressive soils. Similarly, all soils with a mean soluble iron content of over  $120\ \mu\text{g g}^{-1}$  were found to be aggressive. A particularly corrosive situation occurs when  $\text{H}_2\text{S}$  diffuses upwards into the aerated zone, where it becomes oxidized by air to elemental sulfur.<sup>22</sup> An example of external MIC of a cast iron water main is shown in [Figure 5](#). This was one of the most rapid incidences of its kind that has been observed and was accompanied by deposition of elemental sulfur. The site was made-up ground on a new housing estate in the south of England, where the soil type should have been 'nonaggressive' by the foregoing criteria. In fact, the lower horizons were waterlogged with sulfate-rich spring water and the SRB were highly active.  $\text{H}_2\text{S}$  diffused upwards into the aerated zone, where it became partly oxidized by the air to elemental sulfur.

Numerous examples of corrosion of stainless steel and higher active/passive alloys involving sulfide production by SRB have been published.<sup>23,24</sup> The mechanism is discussed in [Section 2.20.4.3](#).

Copper alloys are highly susceptible to rapid and severe biogenic sulfide corrosion if conditions allow the growth of SRB (see [Section 2.20.4.4](#)).

**Figure 4** Typical morphology of SRB-mediated MIC of carbon steel, an example from sheet steel piling.

**Figure 5** Massive 'black water' corrosion of pipe work under wet lay up because of SRB activity.

### 2.20.4.2 Mechanism of SRB Corrosion of Iron and Low-Alloy Steel

The mechanism of SRB-mediated sulfide corrosion of ferrous metals<sup>25</sup> involves both  $\text{H}_2\text{S}$  and  $\text{FeS}$ . CRs tend to be slow at first and then accelerate with time.<sup>26</sup> Initially, semiprotective iron sulfide layers form, which typically reduce the generalized CR compared with sulfide-free environments. Later, sometimes after an exposure period of months, the iron sulfide layer spalls locally and never reforms; in the case of petroleum production pipelines, this localized spalling may be initiated by sand erosion. The remaining iron sulfide film is both electrically conducting and cathodic to carbon steel, thus galvanic attack initiates at the site of the iron sulfide film breakdown, driven by the huge surface area of the  $\text{FeS}$  cathode. Costello<sup>20</sup> has argued convincingly that the principal cathodic reactions are as follows rather than the mechanism of hydrogen ion reduction:

This postulate is supported by the relative pH independence of SRB-mediated sulfide corrosion, except where the pH of the environment is too high or too low to permit SRB growth.

This mechanism is thus a combination of ‘Type (a)’ MIC, direct chemical action of a metabolic product, in this case  $\text{H}_2\text{S}$ , and ‘Type (b)’ MIC (see [Section 2.20.3](#)), the generation of an electrochemical cell, in this case an iron or steel anode with an iron sulfide cathode.

Furthermore, the hydrogen evolved from the cathodic part of the reaction can be used as a source of reducing power by many strains of SRB and coupled to sulfate reduction to generate even more sulfide, a process that is catalyzed by the hydrogenase enzyme. The overall process thus becomes a type of feedback loop: the more the hydrogen available, the more the sulfide generation; the more the sulfide, the more the corrosion; the more the corrosion, the more the hydrogen generated; and so forth. A classic example of this is the so-called ‘black water corrosion’ of carbon steel pipe work under long-term wet lay up (most especially, following hydrostatic testing), in which more iron sulfide may be generated compared with the stoichiometric amount of organic carbon that is available to ‘fuel’ sulfate reduction ([Figure 6](#)). A schematic representation of the mechanism of SRB-mediated MIC of iron or low-alloy steels is presented in [Figure 7](#).

**Figure 6** SRB-mediated external MIC of a cast iron water pipe accentuated by elemental sulfur.

Some workers have suggested that hydrogenase can even directly depolarize steel surfaces by removal of bound atomic hydrogen. This suggested mechanism, the ‘direct cathodic depolarization theory’ (‘Type (c)’ MIC – see [Section 2.20.3](#)), was very prominent in the early literature on SRB-related corrosion and is still cited by some workers, though it has lost widespread acceptance in the light of work showing that hydrogenase extracts are only active on combined, molecular hydrogen ( $\text{H}_2$ ).

[Figure 8](#) shows a longitudinal section of oilfield water gathering line, which suffered a through wall internal perforation because of SRB-mediated MIC. Note the thick layer of black, iron sulfide corrosion product, which has broken down locally to allow massively concentrated localized corrosion at the resulting anodic site surrounded by an overwhelmingly large volume of cathodic and conductive  $\text{FeS}$ . The surface oxidation of the thick  $\text{FeS}$  layer to give a layer of brown rust (with included elemental sulfur) is due to air exposure of the specimen and is typical.

### 2.20.4.3 SRB-Mediated Corrosion of Stainless Steel Alloys

The phenomenon of severe SRB-mediated MIC of stainless steels and higher active/passive alloys is best termed as microbially assisted, chloride-induced pitting attack. It should not be confused with the related but separate mechanism of pitting and crevice corrosion of these materials promoted by aerobic biofilms in seawater, which is discussed in [Section 2.20.6](#). SRB-mediated effects are generally more rapid and severe.

**Figure 7** SRB-mediated galvanic corrosion cell.

**Figure 8** SRB-mediated internal MIC of an oilfield water gathering line.

Active/passive alloys are susceptible to localized pitting by chloride ions. Reduced sulfur compounds produced by SRB, primarily sulfide but also traces of other substances such as thiosulfate, are believed to bind to the metal surface and catalyze the initiation of the stable pitting process at much lower chloride concentrations and at lower temperatures than would otherwise be the case. Once a pit is established, the anodic reaction generates acidic conditions, accelerating the CR and causing flask-shaped cavities to form. This is totally different from the shallow pitting attack of low-alloy materials exemplified in [Figures 4, 5 and 8](#). The pits may be concealed beneath ferric hydroxide and the process is often associated with copious amounts of brown colored biological slime, containing iron-oxidizing bacteria known as *Gallionella*. Bacterial metabolism is only

**Figure 9** Microbially assisted chloride-induced internal pitting attack on AISI 304 stainless steel pipe work showing classic flask-shaped pit.

involved in the pit initiation stage. Once the pit has formed and acidic chloride conditions develop within, the pit propagation process is the same as with any other case of chloride-induced pitting. Claims that MIC of stainless steels is characterized by a particular pit morphology that is different from conventional chloride-induced pitting attack should therefore be viewed with scepticism.

An example of this type of corrosion occurred when AISI 304 grade stainless steel pipe work was installed at a newly built chemical plant in the tropics ([Figure 9](#)). A hydrostatic pressure test was made using local water, which was subsequently left *in situ* in a static condition for several weeks. The 5 mm thick wall pipe work began to leak in hundreds of places at the 6 o'clock position. Initially, futile attempts were made to clamp the pits but much of

the pipe work eventually had to be replaced. The pipes were found to contain slime masses of iron-oxidizing bacteria of the genus *Gallionella* (Figure 10). The aerobic iron bacteria had depleted all the dissolved oxygen, allowing SRB to become active, giving rise to sulfide formation. The water was warm, stagnant, but relatively low with respect to chloride ion concentration ( $20\text{--}30\text{ mg l}^{-1}$ ); the presence of the extensive slime had allowed an inorganic chemical mechanism to initiate and run rife at chloride levels that would conventionally be regarded as relatively safe. This case history stands as a good example of the interaction of 'microbiological' and 'conventional' corrosion processes.

#### 2.20.4.4 MIC of Copper and Copper Alloys

There is a widespread belief that copper and its alloys are toxic to microorganisms and are therefore not susceptible to MIC. This notion is false; copper alloys are much less toxic to bacteria than they are to macrofouling organisms such as seaweed or shellfish; they suffer severe attack by sulfide if conditions allow the growth of SRB. 'Under-deposit' or 'under-fouling' pitting corrosion of copper–nickel heat exchanger tubes due to biogenic sulfide, produced by SRB, has frequently been observed.

Figure 11 shows a gunmetal impeller located in a polluted harbor, which failed in a matter of weeks after the pump was switched off because of growth of SRB in the stagnant pump. The component had previously given 2 years of trouble-free operation in aerated seawater.

Numerous cases of mysterious 'under-deposit' or 'under-fouling' pitting corrosion of copper–nickel heat exchanger tubes have been observed, especially

in marine environments. Many of these failures are demonstrably due to biogenic sulfide produced by SRB. Copper–nickel alloys are much more susceptible to the initiation of MIC by SRB-generated sulfides during the first few weeks of exposure to the operating environment, at which time the protective oxide film is incompletely formed. MIC of aged copper–nickel alloys, with a well-formed oxide film, is also known, but is much less common than for newly exposed material and seems to require considerably more severe conditions, that is exposure of higher concentration of sulfide for a longer duration. The promotion of protective oxide films and avoidance of exposure to stagnant contaminated water during early exposure is critical in order to avoid such problems. If wet lay up with contaminated water is unavoidable, the use of an organic biocide treatment is highly recommended.

Although the most severe corrosive effects on copper alloys, including cupronickel, have typically been associated with microbially generated sulfides, attention has also been drawn to other activities of surface-associated microbial populations, which in some cases can lead to localized corrosion. These are the production of acidic metabolites, the binding of copper by microbial cells and their extracellular slimes, and the alteration of the nature and porosity of the oxide layer because of biofilm penetration. In particular, it should be recognized that the level of acidity at the biofilm metal interface may be much higher than that of the bulk fluid. It has been reported that a biofilm-forming marine bacterial species increased the corrosion potential of copper by 145 mV and the CR fivefold in a seawater medium and that electrochemical impedance spectroscopy data has shown CRs under biofilms in water of pH

**Figure 10** *Gallionella* slime mass from corroded AISI 304 stainless steel pipe work.

**Figure 11** SRB-mediated sulfide corrosion of a gunmetal pump impeller.

8 to be equivalent to those observed under abiotic conditions at pH 6.8.

It is worth noting that when copper alloys are electrically linked into a cathodic protection system they tend to lose their antifouling properties and become highly susceptible to attack by biogenic sulfide produced by SRB colonies underneath the consequent fouling 'mat.'

From the mid 1980s onward, a distinctive type of localized corrosion has been seen in copper pipes carrying potable water, which Campbell and coworkers<sup>27</sup> termed 'Type 1½' pitting. Type 1 and Type 2 are relatively well-known forms of pitting corrosion in copper water pipes; Type 1 occurs in cold water and is associated with the presence of residual carbon films, whereas Type 2 occurs only at temperatures above 60°C, in copper pipes carrying soft water with a sulfate content exceeding the bicarbonate content. The newly identified type of pitting was found to be associated with relatively large mounds of corrosion product and occurred at relatively low temperatures, as in the case of Type 1, but the products consisted principally of basic copper sulfates and black cupric oxide, as in Type 2. The phenomenon was initially reported from Britain, Germany, Sweden, and the Middle East, and in all cases, a gelatinous film of microbial origin and consisting largely of polysaccharides was present.

This occurrence has since been reported from numerous other locations<sup>28</sup> and is commonly associated with blue water, in which the copper concentration in solution can reach tens of milligrams per liter. This should not be confused with 'Type 3' pitting, associated with soft waters and elevated pH (above 8.0), which is also known as blue water corrosion.

The occurrence of this type of copper corrosion has been convincingly demonstrated to be associated with the presence of biofilms comprising extracellular polymeric products of various types of aerobic heterotrophic bacteria, particularly members of the genera *Pseudomonas*, *Sphingomonas*, or *Acidovorax*.<sup>28,29</sup> When the corroded copper surfaces are treated with 25% nitric acid in a similar manner to a carbon film test, a clear gelatinous membrane of biofilm floats on the surface of the acid. This corrosion mechanism is also critically dependent on water composition and operating conditions. Soft waters with less than 40 mg l<sup>-1</sup> hardness expressed as CaCO<sub>3</sub>, low bicarbonate alkalinity (< 20 mg l<sup>-1</sup>), high organic content, mean temperatures of between 20 and 45°C, frequent stagnation, and lack of chlorination or chlorine depletion are factors that favor this

mechanism. One distinctive characteristic is that this type of copper tube corrosion does not have the likelihood of failure at maximum between 1 and 3 years of installation, unlike other common mechanisms.

The mechanism of copper tube failure associated with non-SRB biofilms is still uncertain. Certainly, the uronic acid carboxyl residues of the extracellular biopolymers are rather acidic (typical pK<sub>a</sub> values are in the range 4.2–5.6)<sup>28</sup> and their uronic acid or pyruvyl substitutions are known to possess high affinity binding sites for copper.<sup>30</sup> Furthermore, the heterogeneous nature of aerobic biofilm distribution is certain to create oxygen concentration cells. Siedlarek et al.<sup>31</sup> called attention to the property that oxygen and carbon dioxide, but not chloride ions, can readily pass through the biofilm layer. This allows the formation of copper oxides or hydroxides beneath the biofilm coating but not the deposition of copper (I) chloride. Therefore, it is argued, amorphous copper (I) oxide, which inhibits anodic metal dissolution, cannot readily be formed from hydrolysis of copper (I) chloride in the presence of chloride impermeable biofilm. It is likely that all the foregoing mechanisms play a role to a greater or lesser extent and that they are interactive with one another.

Optimization of the anion ratio in the water with regard to chloride, sulfate, and bicarbonate, minimizing stagnation, ensuring adequate chlorination, and avoiding warming of cold water pipes from proximity to hot water pipe runs are considered to be appropriate measures to minimize the risk of biofilm-related corrosion of copper pipework in potable water systems.<sup>28</sup>

## 2.20.5 Microbially Influenced Acid Corrosion

### 2.20.5.1 Sulfuric Acid Corrosion by Sulfur-Oxidizing Bacteria

Massive and rapid general corrosion of metal, concrete, or limestone under aerobic conditions may be caused by the action of sulfuric acid formed by the oxidation of sulfur or sulfide by members of the bacterial genus *Thiobacillus*. The sulfur-oxidizing bacteria belong to an unusual group of microorganisms called chemolithotrophs. These microorganisms obtain energy not by oxidation of organic compounds but by oxidation of inorganic sulfur compounds (including sulfides) to sulfuric acid; they build up their cell material by fixation of carbon dioxide, and hence they are classed as autotrophs. Purkiss<sup>32</sup> stated that the following interlinked reactions are

performed by mixed cultures of *Thiobacillus* acting on elemental sulfur or sulfides:

Certain of the *Thiobacillus* species will also leach sulfide mineral ores according to the following reaction<sup>33</sup>:

The important points to note are that these bacteria require oxygen (the opposite of the situation with SRB) and a source of reduced sulfur. The end product is sulfuric acid; one species (*Thiobacillus thiooxidans*) has been claimed to remain active at a pH value as low as 0.7, corresponding to more than 5% sulfuric acid.<sup>34</sup> In the author's experience, such an observation would be very unusual, a pH limit in the order of 1.5–2.0 being more common.

Thiobacilli are fairly commonly encountered in nature; it is believed that they obtain their energy from simple sulfur-containing breakdown products of sulfide minerals or from sulfide produced in an adjacent locality (or in the same locality under anaerobic conditions) by SRB. Normally, they are not found in large numbers, but if a high concentration of a suitable nutrient substrate occurs locally, their activity may be great and result in a zone of intense acidity. Such conditions can most commonly arise in sewage, in which sulfide concentration may be high owing to the action of putrefactive bacteria, unless aeration is efficient. Suitable conditions can also arise locally in paper mill effluents, damp or wet sulfur cargos, and 'made-up' ground into which industrial waste material sometimes finds its way. For this reason, sulfuric acid corrosion of underground pipelines is sporadic and unpredictable. Though *Thiobacillus*-mediated corrosion is occasionally encountered in other industrial situations, such as cooling water systems, such instances are surprisingly uncommon.

At first sight, it might seem inconsistent that various microorganisms can obtain energy both from the oxidation of sulfide to sulfate and from the oxidation of sulfate to sulfide. However, the answer is that one chemical reaction is not simply the reverse of the other: sulfur oxidizers consume oxygen, whereas SRB consume organic carbon. The two reactions can be summarized as follows:

Combining reactions [9] and [10] one derives the following overall reaction [11], a variant of the familiar air oxidation of organic carbon to  $\text{CO}_2$ .

Figure 12 shows a severe example of internal corrosion of a mortar-lined ductile iron sewage water pipe, which failed by sulfuric acid corrosion due to the activity of *Thiobacillus* sulfur-oxidizing bacteria. As it is typical, the attack has occurred in the air gap at the top of the pipe where there is no actual sewage contact. Figure 13 explains how this occurs. The rate of microbial activity in the sewage effluent is sufficiently high that the rate of consumption of oxygen exceeds its rate of replenishment by diffusion from the air space. SRB then become active and produce  $\text{H}_2\text{S}$  – some of which diffuses into the air space at the top of the line where it redissolves in a surface film of condensed moisture. The sulfur oxidizers convert the  $\text{H}_2\text{S}$  containing solution to sulfuric acid, which then attacks the metal. Corrosion takes the form of generalized thinning around the '12 o'clock' position.

#### 2.20.5.2 Acid Attack on Concrete

Attack on concrete by sulfuric acid produced by sulfur-oxidizing bacteria of the genus *Thiobacillus* can be a severe problem. The most widely studied problem is the collapse of concrete sewers. As in the case of attack

**Figure 12** Corrosion of a mortar-lined ductile iron wastewater pipe because of activity of *Thiobacillus*.

**Figure 13** MIC processes leading to collapse of iron or steel sewer pipes.

on metallic sewer pipes, this occurs due to growth of SRB in the anaerobic sewage, giving rise to  $H_2S$ . The gaseous  $H_2S$  migrates to the air space at the top of the pipes where it is converted to sulfuric acid by the sulfur oxidizers, leading to low pH, rapid dissolution of the concrete, and collapse of the sewer from the top. Under favorable conditions for the bacteria, average concrete dissolution can be greater than 12.5 mm in 50 years, with higher local rates at the air/sewage interface.<sup>36</sup>

When steel reinforcing bars are exposed, metal corrosion occurs, leading to spalling and cracking of the concrete.<sup>35</sup> Corrosion of reinforced concrete on offshore installations is a more recent problem. In seawater displaced crude oil storage tanks, crude oil stimulates SRB, with sulfur oxidizers again producing sulfuric acid in aerobic zones.<sup>37</sup>

### 2.20.5.3 Acid Corrosion by Fungi

A completely different type of microorganism to the various groups of bacteria is the fungi. The cells are much larger and grow in dense mats of material. Filamentous fungi are aerobic in nature and are involved in a wide range of biodeterioration problems; timber, paper, fuel oils, cloth, etc., can all be attacked by fungi. Fungal activity generates organic acids, leading to a low pH in the surrounding water and under the microbial mat. In addition to direct acid corrosion, oxygen concentration cells are set up between zones of metal covered with oxygen-depleted fungal mats and those areas where no fungi are present. This electrochemical cell drives the metal dissolution reaction beneath the fungal mat. A further complication is that SRB can sometimes proliferate in the oxygen-depleted niches beneath the fungal mats, giving rise to a

combination of acid corrosion enhanced by sulfide corrosion and differential aeration effects.

By far the most troublesome fungus in engineering systems is a type regularly called *Cladosporium resinae*, though now formally reclassified as *Hormoconis resinae*. *H. resinae* has the ability to thrive in the presence of kerosene and other hydrocarbons, which it uses as a carbon source for oxidation. It also produces spores that can survive extremes of temperature, only to germinate when more moderate conditions prevail. *H. resinae* is a continuing problem in fuel storage tanks and in aluminum integral fuel tanks of aircraft.

Brown slimy mats of *H. resinae* may cover large areas of aluminum alloy, causing pitting, exfoliation, and intergranular attack because of the organic acids produced by the microbes and differential aeration cells. This type of problem is largely confined to tropical, humid locations and is particularly severe in short-haul aircraft and those that experience a lot of idle time where condensation builds up.

The above problem was unknown until the 1950s, when it became prevalent after the introduction of gas-turbine-engined aircraft that use kerosene rather than gasoline as a fuel and the adoption of integral or 'wet wing' fuel tanks to replace the earlier rubberized fabric 'bay tanks.'<sup>38</sup> The problem of fungal growth in the fuel tanks of jet aircraft has generally diminished as the design of fuel tanks has improved to facilitate better drainage of condensed water and as biocides such as organoboranes have gained acceptance as fuel additives. However, this type of corrosion has reappeared in recent years, due to increasingly stringent environmental restrictions of biocides in fuel, combined with certain aircraft designs in which the lessons that were learned during the 1950s and 1960s

about the importance of efficient water drainage in integral fuel tanks have seemingly been forgotten.

### 2.20.6 MIC of Higher Alloys by General Aerobic Biofilms in Natural Seawaters

While the most rapid and severe MIC attack of stainless steels and higher active/passive alloys is commonly associated with SRB (see [Section 2.20.4.3](#)), several investigators<sup>39–42</sup> have reported positive shifts in the open circuit potentials for metals exposed to natural seawater. This positive shift has been attributed to the development of general mixed bacterial slimes on the exposed metal surface. A wide range of bacteria (e.g., *Pseudomonads* and *Flavobacteria*) can secrete large amounts of slime-like organic material under both aerobic and anaerobic conditions. Although the exact mechanism by which the bacterial film enhances the oxygen reduction kinetics is not fully understood, it has been postulated that the oxygen reduction is catalyzed by enzyme action, leading to either an increase in the exchange current density or a decrease in the cathodic Tafel constant.

In the absence of corrosion, the free corrosion potential of high molybdenum austenitic and duplex stainless steels in artificial seawater was found to rise from  $\sim -100$  to  $0$  mV and reach a stable value of  $\sim 130$  mV (vs saturated calomel electrode) after  $\sim 10$  days.<sup>42</sup> In microbially active seawater, however, there appears to be fairly common agreement that the potential continues to rise and reaches stable values of  $300 \pm 50$  mV after 20 days. There are indications, however, that the final potential is relatively independent of composition but is dependent on factors such as temperature and flow rate.

The length of time to reach the steady potentials has been shown to be closely related to the time necessary for microorganisms to settle and grow on the metal surface. Close examination of some of the potential versus time curves reported in the literature reveals that there is an initial rise in potential in the first 2–3 days, followed by a more rapid rise until the potential stabilizes after  $\sim 20$  days. This is consistent with the time found by Gunderson *et al.* for the bacterial count to reach a level of  $\sim 10^6$  cells  $\text{cm}^{-2}$ .

The effect of the potential rise because of bacterial slime is to increase the susceptibility of these alloys to crevice corrosion, but this is accompanied by an increase in the cathodic reaction rate, and therefore,

once crevice initiation occurs, there can be a marked increase in the crevice propagation rate.

Temperature has a number of important effects. First, the rate at which a critical crevice solution (CCS) is achieved is believed to be a function of the passive current density within the crevice, which may be increased by 2–3 orders of magnitude because of the positive potential shift caused by bacterial slimes compared with sterile seawater. It may also increase by 1–2 orders of magnitude because of an increase in temperature from  $10$  to  $35^\circ\text{C}$ . Second, it is reported that there is a maximum temperature for biofilm growth of  $\sim 30$ – $32^\circ\text{C}$ , although this may be higher in warm climates such as the Mediterranean because of greater natural tolerance.

This phenomenon explains why the crevice CRs for 254 SMO and SAF 2507 have been found to be 2–3 decades higher at  $25^\circ\text{C}$  than at  $40^\circ\text{C}$ . At lower temperature, the biofilm activity increases the potential, and therefore increases the risk of crevice initiation, but also increases the cathodic reaction efficiency and consequently increases the rate of propagation. At  $40^\circ\text{C}$ , the higher temperature also increases the risk of crevice initiation but the loss of the biofilm activity results in lower cathodic efficiencies and lower propagation rates. The anodic current densities were found to be 2–3 decades higher at the lower temperature. Mathematical modeling was used to show that, in the absence of biofilms, a much larger cathode-to-anode area ratio was required to sustain high CRs, and that improved mass transport of oxygen because of higher flow rates had a greater effect on the propagation rate than in the presence of the biofilm.

### 2.20.7 Other Microorganisms Associated with MIC

As already discussed, biological slimes are commonly found in the water phases of industrial process plant. Conditions at the base of even thin slimes can be anaerobic and therefore ideal for the growth of SRB, with high organic nutrient status, oxygen depletion, low redox potential, and protection from biocidal agents. In such situations, SRB-mediated sulfide corrosion can be exacerbated by fermentative acid production. An illustration of how easy it is for anaerobic conditions to develop even beneath thin microbiological slime layers is provided by the well-known process of tooth decay; the secretion of organic acids, which leads to such dental decay, is a completely anaerobic process – in the presence of oxygen, sugars

are oxidized to carbon dioxide instead of being fermented to produce acids. Given that even a thin layer of tooth plaque can give rise to anaerobic conditions, it can be appreciated how colonies of the strictly anaerobic SRB can similarly thrive beneath slimes in the nominally fully aerated environments of industrial water systems.

A particularly common type of biological slime is that produced by iron bacteria, which are found in freshwaters with a high concentration of reduced iron compounds. The bacteria require aerobic conditions and form colonies that are impregnated with ferric oxides. *Sphaerotilus* forms dense, cotton wool like growths in organically polluted rivers, the bacteria forming filaments, which are surrounded by a sheath of slime and iron oxide. The base of the colony may be highly anaerobic and SRB can develop under certain conditions. Another genus of iron bacteria, *Gallionella*, is able to use iron sulfides as a source of reduced iron, and is therefore commonly found in association with SRB. The consortium, in the form of tubercle, is one of the classic examples of growth of organisms inside ferrous water pipes.

Some components of slimes also use nitrogen-containing compounds as an energy source. They are involved in the cycling of nitrogen in the environment. Ammonia and amines are produced by microbial decomposition of organic matter under both aerobic and anaerobic conditions (ammonification). These compounds are oxidized to nitrite and nitrate by aerobic bacteria such as *Nitrosomonas* or *Nitrobacter* species. *Nitrobacter* is very efficient at destroying the corrosion-inhibition properties of nitrite-based inhibitors by oxidation of nitrite to nitrate, unless a biocidal agent is included in the inhibitor formulation.<sup>43</sup> Whereas under anaerobic conditions, a wide range of bacteria can reduce nitrite to nitrogen gas, sometimes with the production of ammonia as a by-product. The detrimental effects on brass by the release of ammonia at the surfaces of heat exchanger tubes have also been highlighted.<sup>44</sup>

### 2.20.8 Testing for MIC Activity

Assessment of a microbial population in industrial fluids is normally carried out by the use of well-established culture techniques involving specific growth media; this test format was developed for oil-field water systems, but is suitable for other industrial situations as well. Enumeration of SRB and total viable bacteria is most commonly by a 'serial extinction

dilution technique' in liquid media, using vials containing specially formulated SRB growth medium.<sup>45</sup> The test comprises initially a *serial dilution step*, followed by an *incubation step*. Ideally, the serial dilution part of the test should be carried out within a few hours of obtaining the subject samples (typically done on site); however, this is frequently not possible. The results become less reliable with increasing sample age. At the end of the incubation period, the SRB population density in the original sample is determined to the nearest order of magnitude by the number of vials in each dilution series that turn black because of bacterial sulfide production. According to current standards, the prescribed incubation period for SRB is a minimum 28 days, but a very good indication of the SRB count can usually be obtained after 10–14 days of incubation.

An example of an SRB serial extinction dilution set is shown in **Figure 14**. Similar serial dilution tests, using a different type of growth medium, are used to enumerate total bacteria; the vials that show growth turn cloudy rather than black, often accompanied by a color change of an indicator dye to indicate organic acid production.

For the most accurate assessment, threefold or fivefold replicate serial dilution enumeration is carried out; this allows the mean probable number (MPN) of bacteria to be derived from standard MPN tables. Test kits of this type are commercially available, sometimes in a simplified form. There are also some rapid assay kits based on antibody reactions to SRB enzymes, which do not require an incubation period to obtain a result. All simplified and rapid kits compromise accuracy and reliability to a greater or lesser degree. They should be regarded as no more than crude indicators, unless calibrated against standard serial dilution techniques for a specific environment.

Most of the SRB and other bacteria present in industrial systems are sessile. Planktonic bacterial

**Figure 14** Serial dilution test for SRB, blacking (positive SRB count) to 5 orders of magnitude demonstrates heavy infestation.

counts are often misleadingly low, whereas much larger populations may be concealed in sediments, deposits, and biofilms on metal surfaces. Increasingly, there is a trend to monitor SRB, and microorganisms generally, using metal coupons similar to corrosion test coupons. Such coupons are sometimes termed 'bioprobes' or 'biostuds,' and for ease of recovery, are often placed in side-stream devices in flowing pipelines (Figure 15).

If surface deposits or coupons are available, they should be sonicated or scraped into vials of culture media, serially diluted on site, then incubated in the manner of water samples. In order of priority, samples from industrial systems should be taken from bottom, metal surfaces, dead ends, and sumps. Sampling should be on a regular basis, weekly, monthly, or quarterly, depending on the extent of concern.

Low sessile population counts of below  $\sim 1000$  SRB colony forming units (cfu) per gram of deposit or per square centimeter of surface are not levels about which much concern need be expressed. However, periodic testing should be undertaken to check trends. Populations will oscillate, but if they show a general upward drift, then action will be necessary sooner or later.

Planktonic SRB counts provide a less reliable indicator than do sessiles. However, recurrent counts of greater than  $\sim 10$  cfu ml<sup>-1</sup>, any general upward trend, or any positive planktonic SRB counts in a nominally biocide-treated system are a cause at least for further investigation of sessiles. Any planktonic SRB counts above  $\sim 1000$  cfu ml<sup>-1</sup> is indicative of a heavy

proliferation somewhere in the system, probably in deposits on surfaces, especially in stagnant or low flow areas.

Total viable bacteria counts (TVCs) are usually much higher than SRB counts. Planktonic TVCs of up to 100 000 per milliliter are common in many natural waters and industrial systems. Higher population densities, greater than 100 000 per milliliter probably, indicate a significant build-up of slime somewhere. In biocide-treated systems, TVCs should be several orders of magnitude lower than in the untreated water. The incubation period for TVCs is only  $\sim 3$  days, considerably shorter than for SRB. Therefore, these counts can give a useful early warning of any problem with biocide-treatment efficiency.

SRB counts and TVCs are relatively straightforward, routine analytical techniques. Tests for nitrite-utilizing bacteria or sulfur oxidizers are more complex, specialist techniques. However, problems associated with these organisms are usually clearly evident from the undesirable chemical changes they bring about.

As a supplement to microbiological testing, it is useful to carry out some chemical analyses. An important test is for sulfide in corrosion deposits. In the case of iron sulfide, a simple test is to warm a small sample of the solid with a few milliliters of 50% hydrochloric acid in a glass test tube. If sulfide is present in the deposit, a slightly moistened strip of lead acetate paper in the mouth of the tube will turn brown, indicating H<sub>2</sub>S evolution. If a lot of sulfide is present, the characteristic 'rotten egg' odor will also be apparent.

**Figure 15** A typical side stream device incorporating 'biostuds' for monitoring of biofilms.

This test needs to be undertaken within a short time of removing samples of deposit from the corrosion site, because wet or damp iron sulfide will eventually oxidize in air to brown rust. The color change of corrosion deposits from black to brown is, in itself, a good indication of sulfide corrosion product. Any such deposits that are taken back to the laboratory for more sophisticated chemical analysis should be preserved in anaerobic bags to prevent the oxidation of FeS, which would otherwise occur.

Tests for sulfate, total organic carbon (TOC), pH, and oxygen concentration are also useful indicators of the potential for SRB growth. If sulfate concentration is low, then there is little hazard of SRB activity. The pH range most suited to SRB growth is 5–10. Outside these limits, bulk phase growth of SRB is very limited. Oxygen concentration will also affect SRB growth in bulk phases but a high value does not mean that SRB are not present in pockets or under debris. A high oxygen concentration may allow other organisms to develop. The interpretation of those tests, together with other operating parameters, is discussed in [Section 2.20.9](#).

## 2.20.9 MIC Risk Assessment Based on Operating Conditions

It is frequently the case that the engineer is required to make an appraisal of MIC risk with limited information on the corrosion history and little or no historic microbiological test data. The conclusions that may be drawn about the risk of MIC in such cases are largely based on consideration of operating parameters. This is often the situation for the assessment of internal corrosion risk of pipelines, water handling systems, or process plant. The discussion that follows refers specifically to SRB-related problems, which are by far the most common MIC issue.

A group of researchers at Shell Petroleum Co. have developed an approach to risk assessment of carbon steel pipelines, based on the details of water chemistry and operation parameters.<sup>46</sup> Their MIC CR calculation is based on the following equation:

$$\text{CR}(\text{mm year}^{-1}) = C \times F^p \quad [12]$$

with

$$F = f_1 \times f_2 \times \cdots \times f_n \quad [13]$$

where  $C$  is a constant ( $C = 2 \text{ mm year}^{-1}$ ), the  $f$ s are factors for the various influencing parameters and  $p$  is a power law index (0.57).

Although such an approach does provide a valuable empirical recognition of the relative contribution of the factors that encourage or inhibit MIC, the calculation of actual CRs on such a basis should be viewed with extreme caution, given our present limited understanding of the effects of the various factors, the most important of which are discussed below.

### 2.20.9.1 Presence of Water

All bacteria require free water in order to proliferate. In the case of oil pipelines, MIC is to be considered only under separated flow conditions; if all water is entrained in the hydrocarbon, there is no risk of MIC.<sup>46</sup> In the author's experience, it is unwise to rely on dispersions to provide fully oil-wetted surfaces when the bottom solids and water content (BS and W) is in the order of 2% or greater, except under very turbulent hydrodynamic conditions. It is best to take an empirical and conservative view as to whether lines may be wet enough to sustain SRB growth at the present time and during their future operating life.

### 2.20.9.2 Salinity

According to results presented by Postgate,<sup>14</sup> if the salinity of water, expressed as w/w percentage NaCl, is more than ~7%, there is unlikely to be any SRB growth. That observation broadly agrees with the author's own experience and similar statement is reiterated in the more recent Shell Petroleum Co. work.<sup>39</sup> However, it should be noted that other workers have suggested that some SRB strains may tolerate considerably higher salt concentrations.

### 2.20.9.3 Temperature

Most types of bacteria grow optimally at temperatures between 10 and 45 °C, which is the highest risk temperature range. However, there are thermophilic strains of SRB and some other microorganisms that grow at higher temperatures up to at least 70 °C and their activity cannot be discounted.

### 2.20.9.4 pH

Generally, there is unlikely to be SRB proliferation below pH 5 or above pH ~10, though the pH range for SRB that are protected in heavy deposits may be somewhat wider.

### 2.20.9.5 Anaerobic Conditions

SRB will only proliferate and produce sulfide in the absence of oxygen. Clearly, deaerated environments are at greatest risk; however, there are many cases of problems in slimes and deposits where the bulk water phase is essentially aerobic, for example, in cooling waters. This is especially the case for static or slow flow conditions.

### 2.20.9.6 Nutrient Status of Water Phase

SRB growth is much less likely if the aqueous sulfate concentration or the organic carbon content is below  $\sim 10 \text{ mg l}^{-1}$  or the ammoniacal nitrogen (not nitrate or nitrite) is below  $\sim 1 \text{ mg l}^{-1}$ . An exception, in the author's experience, is the case of plant under long-term lay up with static, high-sulfate water (e.g., seawater), where a corrosive 'black water' condition may develop over a period of months even with very low organic carbon content. This is believed to be due to reduction of sulfate by SRB using cathodic hydrogen formed by corrosion on steel surfaces.

### 2.20.9.7 Flow Rate

Flow rate influences the nature of biofilm formation and the rate of nutrient delivery. As flow rate increases, biofilms become less bulky and only the more adherent films remain on the metal surface. However, above a certain threshold, the initiation of biofilm formation is severely limited. The transition zone is considered to be between 2 and  $3 \text{ m s}^{-1}$ . At the other extreme, stagnation is often associated with the severest MIC incidents.

### 2.20.9.8 Cleaning Frequency

As discussed earlier, in order to initiate the MIC process, the free-floating ('planktonic') SRB cells need to attach to a metal surface (i.e., become 'sessile') and proliferate to form a biofilm with its own entrained microenvironment. It is that process that is disturbed by regular mechanical cleaning, such as brush 'pigging' of pipelines. The incipient biofilm is disrupted and largely removed and this *is the most* effective means of minimizing SRB growth and obviating MIC. MIC is uncommon in pipelines that are frequently pigged, even without biocide treatment. The more frequent the pig runs, the less time the biofilm has to recover.

### 2.20.9.9 Use of Antimicrobial Chemical Treatments

Any operation that disrupts the biofilm and thereby limits its proliferation will act to alleviate MIC. The application of periodic or continuous biocide or other antimicrobial chemical treatment is one such factor, which is discussed in more detail in [Section 2.20.10](#).

## 2.20.10 Control of MIC

### 2.20.10.1 General Principles

For situations where chemical treatment of the environment by biocides is not possible (e.g., soils, harbors, marine fouling, etc.), the remedies available reflect measures taken to obviate other forms of corrosion and may be summarized as follows.

#### 2.20.10.1.1 Provision of a nonaggressive surround

For buried steel, provision of a backfill of sand or chalk around the material to ensure good drainage and aeration is helpful. Incorporation of a very sparingly soluble biocide into the backfill material has been tried with some success. Another method is to incorporate biocide into protective coatings, the best-known example probably being the use of strontium chromate primers, which are very effective in controlling the kerosene fungus in aircraft wing integral fuel tanks, until such time as the chromate becomes deleted by leaching into the condensed water phase. However, the use of such treatments is both expensive and becoming increasingly less acceptable for environmental reasons.

#### 2.20.10.1.2 Cathodic protection

This may be in the form of sacrificial anodes or impressed voltage, sometimes in conjunction with a coating. There is a long-standing precept, current in the industry, that structures need to be held at potentials more negative than  $\sim -0.9 \text{ V}$  (vs Ag/AgCl) in order to protect against anaerobic corrosion by SRB. Horvath and Novak<sup>47</sup> presented the most reasoned argument for this view, which has appeared numerous times in print, though the evidence is not very convincing.

#### 2.20.10.1.3 Protective coatings

The coating must be resistant to biodegradation and to chemical attack by the metabolic products of microbial activity, principally  $\text{H}_2\text{S}$  and sulfuric

acid. Biodegradation resistance of the more long-established wrappings and coatings forms a separate study and was the subject of a site study by British Gas in the 1970s.<sup>48</sup>

#### 2.20.10.1.4 Biocides

For internal protection of pipelines, cooling systems, vessels under hydrotest, etc., biocide treatment is the obvious remedial measure, in combination with cleaning techniques. Their selection use is explained in more detail below.

### 2.20.10.2 Biocide Treatments

A microbiocide must first be effective in greatly inhibiting microbial activity; second, it must be economical in a treatment program; and third, it must meet the constraints imposed by increasingly stringent environmental legislation. In Europe, the availability of biocides is now restricted to a limited range of substances that are registered under the European Union's 'Biocidal Substances Directive,' which was primarily intended for control of agricultural pesticides but has caught industrial biocides within its net.

Biocides can be broadly divided into two types: oxidizing and nonoxidizing. Commonly accepted oxidizing biocides are 'chlorine' (actually mainly hypochlorous acid plus hypochlorite ion), chlorine dioxide, chlorine donors, bromine, ozone, and hydrogen peroxide. Chlorine is by far the single most prevalent industrial biocide in use today; it is popular because of its efficiency, low cost, and relative environmental acceptability. The disadvantages of chlorine are its high reactivity with many other chemicals, short half-life, necessitating continuous dosing of flowing systems, and difficulties with dosage control – there is a narrow window between the effective dose and an overdose, which can give rise to serious corrosion problems for a wide range of materials. Achieving a continuous chlorine dose with that 'window,' typically 0.2–1.0 mg l<sup>-1</sup>, is complicated by the 'chlorine demand' of natural waters. During continuous chlorination practice, sufficient chlorine must be generated to overcome the chemical demand and leave a free chlorine residual. This is variously expressed as free residual chlorine (FRC), free available chlorine (FAC), total residual chlorine (TRC), or total available chlorine (TAC). In each case, it is a measure of the residual oxidizing power rather than the true concentration of dissolved chlorine, since a number of different 'free chlorine species' are produced during water chlorination.

Chlorination can be achieved by dosing with chlorine gas or sodium hypochlorite solution and in the case of treating large volumes of saline water by electrolytic chlorine generation. When water is chlorinated, whether by chlorine gas, addition of sodium hypochlorite ('bleach') solution, or by electrolytic generation, it very quickly reacts to establish the equilibrium:

One of the by-products is H<sup>+</sup> and therefore the concentration of OCl<sup>-</sup>, HOCl, and Cl<sub>2</sub> are pH dependent. At a pH of greater than 8, chlorine is present predominantly as OCl<sup>-</sup> (hypochlorite ion), whereas at pH 7.5 there is a mixture of hypochlorite and hypochlorous acid (HOCl) and at lower pH values hypochlorous acid predominates. HOCl is ~80 times more effective as a biocide than OCl<sup>-</sup>, which means that chlorination is more effective as a biocidal treatment for neutral or slightly acidic 'soft' waters than it is for alkaline 'hard' waters. The exception is seawater, which has an alkaline pH of ~8.2 but can, nevertheless, be effectively chlorinated due to the presence of bromide ions, which react with hypochlorous acid to form hypobromous acid (HOBr); 'chlorination' of seawater is really therefore bromination. HOBr has a different pH-dependent dissociation profile to HOCl, making it much less dissociated into OBr<sup>-</sup> ions under mildly alkaline conditions and therefore effective as a biocide in seawater.

Continuous chlorination of industrial water systems might seem prudent for control of MIC as well as slime control on heat exchangers and for public health reasons, particularly the control of the waterborne pathogen *Legionella*, the causative organisms of legionnaire's disease. However, in some high demand systems with process leaks maintaining a continuous 'FRC' level is not economically feasible. The alternative is to maintain a 'FRC' concentration from 0.3 to 0.8 mg l<sup>-1</sup> for up to 2 h per treatment period in order to kill as much as possible of the sessile biofilm. The rate of recontamination will suggest the frequency of treatment.

The shortcomings of chlorination for certain systems with high pH and/or high chlorine demand have led to an increase in the popularity of chlorine dioxide (ClO<sub>2</sub>) as an alternative oxidizing biocide. Chlorine dioxide has more oxidizing power than 'chlorine,' yet is less affected by the chemical composition of the water than is chlorine and it forms a true nonionized solution of a gas, which is not pH dependent. ClO<sub>2</sub> is usually generated at plant site by

the reaction of chlorite and hypochlorite, with the addition of acid to ensure the optimal pH for the reaction. For this reason, it is somewhat more complex and expensive than chlorination. Other oxidizing biocides are less extensively used in industrial water systems, but their mode of action is similar to chlorine and chlorine dioxide.

The alternative approach to the use of oxidizing biocides is to use much higher concentrations of organic, nonoxidizing biocides,<sup>49</sup> often blended with surfactants to increase their penetrating power into biofilms and other deposits. Some of the most common organic biocides are THPS (tetrakis hydroxy phosphonium sulfate),<sup>50</sup> aldehydes (glutaraldehyde and formaldehyde),<sup>51</sup> quaternary ammonium compounds,<sup>52</sup> biguanides,<sup>53</sup> isothiazolones,<sup>54</sup> chlorinated phenols, methylene-bis-(thiocyanate), dithiocarbamates, sulfones, and thiones. All the various types of organic biocides have advantages and disadvantages relative to one another and to oxidizing biocides, which are beyond the scope of this chapter. However, it is worthwhile to elucidate some general principles about biocide selection.

First, where some form of biocide treatment is in use, it should not necessarily be assumed that it must be effective. Biocides have very limited ability to penetrate existing deposits and are therefore much more effective when used in conjunction with frequent mechanical cleaning processes such as brush cleaning or 'pigging' of pipelines.

The first stage of biocide selection is a laboratory evaluation of candidate biocides. For plant under wet lay-up, recirculating water systems, or other batch processes, there are only two parameters that need to be optimized: type of biocide and concentration. However, for oilfield water systems, such as secondary recovery water injection systems, continuous treatment with biocides at an effective dose is not feasible. Continuous low-level injection of organic biocide is of no value; indeed continuous low-level exposure may possibly be detrimental in the long term, because there is some possibility that it may encourage the development of more biocide tolerant strains of bacteria. Periodic batch treatment is therefore required to treat biofilms and this means that there is a substantial matrix of parameters: type of biocide, concentration, duration of batch, and frequency of treatment. The first three factors may be optimized by means of a laboratory 'time kill test'<sup>45</sup> using real or simulated system water at system temperature, bacteria such as mixed cultures of SRB, isolated from the system for which the treatment is

being selected, and most importantly, sessile rather than planktonic populations. More realistic, though more complex and expensive, tests can be performed on side stream units at site. As with batch chlorination, the rate of recontamination will suggest the frequency of treatment and this parameter can only be optimized on the basis of site experience.

Given the relative complexity of optimizing biocide dosages properly, it is not surprising that organic biocides are commonly either underdosed or overdosed. Underdosing ultimately results in lack of control of MIC, possibly involving biocide-resistant strains of microorganisms and negates the whole purpose of the treatment strategy. Conversely, overdosing involves not only unnecessary expenditure over a prolonged period but also the introduction of unnecessarily large amounts of toxic substances into the environment.

### **2.20.10.3 Alternatives to Biocide Treatments**

Given the shortcomings of biocide treatments, specific antimicrobial treatments based on manipulation of microbial ecology have long been mooted; one such alternative, continuous nitrate treatment, has recently become commonplace for selective control of SRB in oilfield water systems. Though mainly employed as an agent against H<sub>2</sub>S generation in deep petroleum reservoirs ('souring'), nitrate (or, less commonly, nitrite) based treatments have also been used in some locations as anti-MIC agents in topside facilities, either alone or in combination with biocide.

The objective of these treatments is the suppression of sulfide generation by the selective manipulation of indigenous bacteria through nutrient addition. There are several possible mechanisms by which nitrate can suppress the accumulation of sulfide.

Nitrate-reducing bacteria (NRB) generally 'out-compete' SRB for common carbon and energy sources such as acetate and longer chained fatty acids. This shifts the flow of electrons in energy-generating metabolism of bacteria away from sulfate reduction toward nitrate reduction. Ideally, this process gives rise to nitrogen as the end product, but sometimes it also results in the production of nitrite.

SRB themselves may preferentially use nitrate instead of sulfate as the electron acceptor in their energy-generating metabolism.

NRB may produce traces of compounds (nitrogen oxides and/or nitrites) that raise the oxidation-reduction (redox) potential of the environment to a

level that is inhibitory to the growth of SRB or these substances may act as toxins to SRB.

Finally, specialized nitrate-reducing sulfide oxidizing bacteria may use the sulfide produced by SRB as the electron donor for nitrate or nitrite reduction. In this case, the production of sulfide is not completely inhibited, but the consumption of sulfide by NRB prevents its accumulation.

Depending on the microbial populations present, any of the above mechanisms or combinations of mechanisms may be operative. The addition of nitrate does not directly kill SRB and, in some cases, will not inhibit their activity, but will still achieve the desired effect – the reduction or removal of sulfide. Several field tests have also demonstrated the potential usefulness of nitrate for controlling SRB. The Institute of Petroleum (now the Energy Institute) in the United Kingdom published a useful introductory review about use of nitrate treatments to control SRB, MIC, and reservoir souring.<sup>55</sup> Certainly, in laboratory tests, these treatments have proven very effective for suppression of SRB activity compared with conventional biocide treatments.

Unfortunately, in practice the use of these agents is by no means always problem free; in particular, the production of nitrites as a by-product of the treatment may itself induce pitting corrosion in a minority of applications; furthermore, nitrate is only active against SRB rather than the wider range of other MIC microorganisms. In summary, it continues to be the case that no single treatment can provide a definitive solution to MIC; the choice of most appropriate agent is very situation specific and will remain, like most decisions relating to living organisms, a challenging compromise.

### 2.21.1 Introduction

Sodium hydroxide (caustic soda) is one of the world's most commercially important chemicals. It is produced in huge quantities worldwide, mostly as a by-product of the electrolysis of brine to produce chlorine, historically in mercury cells but increasingly in diaphragm or membrane cells. Diaphragm cells are used to produce the majority of the world's caustic soda which leaves the cells at ~10–12% (w/w) concentration, and is subsequently evaporated to produce commercial grades, typically at 50% and 73% (w/w) concentration, or anhydrous. Potassium hydroxide (caustic potash) also has some commercial significance but it is more expensive than and, in volume terms, well-behind caustic soda.

Both sodium and potassium hydroxides are strong bases that are highly dissociated in water at all concentrations to release the metal cation and the hydroxide anion as follows:

Their aqueous solutions have pHs above 7, and pHs 10, 11, and 12 are equivalent to concentrations of 4, 40, and 400 ppm (w/w) sodium hydroxide respectively at 25 °C.

Depending mostly on the method of manufacture, sodium hydroxide may contain contaminants that are potentially significant from the corrosion standpoint, in particular:

1. Chlorides, particularly in the case of the sodium hydroxide produced in diaphragm cells that may contain up to 1% (w/w) sodium chloride, in contrast to mercury or membrane cells that deliver sodium hydroxide with much lower levels of sodium chloride, typically 10 s of ppm.
2. Chlorates,  $\text{ClO}_3^-$ , are produced at the anode during electrolysis and are normally removed before or during the evaporation stage in the manufacturing process, so are of significance mostly to the performance of manufacturing equipment.
3. Chlorine and hypochlorite that is formed when chlorine, a coproduct of electrolysis, dissolves in sodium hydroxide:

4. Mercury, entrained in the sodium hydroxide produced in mercury cells.

Alkalis differ fundamentally from acids in the mechanism of the metal dissolution process. In acids, soluble metal cations are produced anodically, supported by hydrogen evolution as the primary cathodic process. In alkalis, soluble oxyanions containing the metal are produced by reaction between the metal and hydroxide anions. In the case of the so-called amphoteric metals such as aluminum, zinc, tin and lead, and their alloys, these processes are so strongly favored as to render the metals unsuitable for service under alkaline conditions because of the formation of soluble aluminates, zincates, stannates, and plumbates respectively. For example, a simplified Pourbaix diagram for the aluminum–water system at 25 °C is shown in **Figure 1**, and confirms that the metal will be potentially vulnerable to corrosion above a pH of  $\sim 9$  as well as below a pH of  $\sim 4$ .

The reactions that give rise to this alkaline vulnerability in aluminum are thought to consist of the initial formation of aluminum hydroxide in a series of three single electron transfers<sup>1</sup>:

The final step is believed to be the chemical dissolution of aluminum hydroxide to form soluble aluminate<sup>1</sup>:

The supporting cathodic process is the direct reduction of water molecules on the aluminum surface with the liberation of hydrogen:

**Figure 1** Simplified potential/pH diagram for the Al–H<sub>2</sub>O system at 25 °C, based on an equilibrium activity of  $10^{-6}$  g ion per litre.

Thus, and somewhat counter-intuitively, hydrogen is produced in the corrosion processes occurring adjacent to the metal surface despite the tiny concentration of protons in the bulk fluid.

The corrosion performances of the various classes of material in alkalis have been reviewed extensively elsewhere.<sup>2–5</sup> Much of the data relates to sodium hydroxide, reflecting its commercial significance. There is relatively little data for potassium hydroxide in the public domain. Readers whose main interest is to identify ‘what works where’ are referred to these sources and the relevant chapters on specific materials in this book. In this chapter, the corrosion performances of materials are reviewed with an emphasis on the principles and mechanisms that underpin their corrosion performances in alkalis.

## 2.21.2 Steels and Cast Irons

The Pourbaix diagram for the iron–water system at 25 °C shown in **Figure 2**<sup>6</sup> suggests that steels should form protective oxide films, probably composed of magnetite ( $\text{Fe}_3\text{O}_4$ ), at pH up to  $\sim 14$ , approximately equivalent to  $\sim 4\%$  (w/w), or 1 M, sodium hydroxide.

When the pH is above 14 the diagram indicates that there is a potential corrosion zone arising from

**Figure 2** Simplified potential/pH diagrams for the Fe–H<sub>2</sub>O system at 25 °C and 300 °C, based on an equilibrium activity of 10<sup>−6</sup> g ion per litre. Adapted from Chen, C. M.; Aral, K.; Theus, G. J. Computer Calculated Potential–pH Diagrams to 300 °C, Report NP-3137, Electric Power Research Institute, 1983.

the stability of the dihypoferrite anion,  $\text{HFeO}_2^-$ , that forms by the anodic dissolution of the metal in a sequence of steps similar to those for aluminum above, culminating in the dissolution of ferrous hydroxide as the dihypoferrite anion, rather than its further oxidation to solid magnetite on the surface. The overall process can be written as follows:

As in the case of aluminum, the supporting cathodic process is the reduction of water to hydrogen. The dihypoferrite anion is in equilibrium with the hypoferrite (ferroate) anion as follows:

This equilibrium moves to the right as the alkalinity increases. Dissolution of the magnetite film also contributes to metal dissolution under alkaline conditions:

In practice, carbon steel is widely used for the storage, handling, and transport of sodium hydroxide solutions at concentrations and temperatures well beyond the limits suggested in the Pourbaix diagram, indicative of a kinetic rather than thermodynamic control over the stability of passivity. Although measured corrosion rates vary with purity, velocity, and other factors, the general experience is that corrosion rates are acceptably low in concentrations up

to ~75% (w/w) at temperatures up to ~80 °C and perhaps even beyond,<sup>5</sup> assuming that some degree of iron contamination is acceptable. Of the potential contaminants, only chlorates present a significant threat, having the potential to accelerate the corrosion of steel by up to an order of magnitude, depending on the concentration.<sup>5</sup>

The major concern across these concentrations and temperatures is not general corrosion but the risk of intergranular stress corrosion cracking (SCC) to which carbon steels are vulnerable in the presence of tensile residual stresses arising from welding and cold working operations during fabrication. These risks can be mitigated by thermal stress relief following fabrication and some well-established guidelines for determining the need, or otherwise, for postweld heat treatment (PWHT) are available and are summarized in [Figure 3](#).<sup>7</sup>

The presence of carbon/carbides in the steel and the segregation of phosphorus at grain boundaries increase the risks of cracking.<sup>8</sup> Low alloy steels vary in their vulnerability to caustic-induced SCC. Tests have suggested that nickel-containing steels are more resistant than carbon steels, molybdenum additions are detrimental and the effects of chromium additions vary with temperature.<sup>9</sup>

At higher temperatures and concentrations, the zone of dihypoferrite stability increases considerably, extending to lower pH values, as shown in the Pourbaix diagram for the iron–water system at 300 °C in

**Figure 3** Temperature and concentration limits for stress corrosion cracking susceptibility of carbon steels in sodium hydroxide solutions. Adapted from NACE Standard Practice SP0403–2008. Avoiding Caustic Stress Corrosion Cracking of Carbon Steel Refinery Equipment and Piping; NACE International: Houston, TX, 2008.

**Figure 2**, which suggests that the alkaline corrosion of steels is possible at a pH down to  $\sim 9$ , equivalent to lightly alkalized water. Kinetic studies suggest that the magnetite film on carbon steels begins to lose its protective properties as temperatures increase above the atmospheric boiling point, depending on concentration. Anodic polarization curves for AISI 1020 steel in stagnant 2.75 M ( $\sim 11\%$  w/w) sodium hydroxide at temperatures in the range 95–175 °C are shown in **Figure 4**.

The active regions of the curves are thought to be attributable to active iron dissolution as ferroate rather than dihypoferrite, because of the greater solubility of the former in alkaline solutions. Although passivation behavior is evident at all four test temperatures, the passive current increases by around an order of magnitude between the lowest and highest temperatures. Additional studies on rotating electrodes suggest that this is due to magnetite film thinning due to increased solubility as the temperature rises. Film formation competes with film dissolution, and turbulence accelerates film dissolution and corresponding corrosion rates.<sup>10</sup>

Although the corrosion risks that are presented at high temperatures by increased concentrations of sodium hydroxide solutions are well understood,

**Figure 4** Potentiodynamic polarization curves for AISI 1020 steel in stagnant 2.75 M ( $\sim 11\%$  w/w) sodium hydroxide at temperatures in the range 95–175 °C. Adapted from Giddey, S.; Cherry, B.; Lawson, F.; Forsyth, M. *Corros. Sci.* **2001**, 43, 1497–1517.

problems can arise in practice in situations where nominally benign concentrations can increase locally under the influence of high heat fluxes and/or adverse geometries, particularly in steam raising equipment. Corrosion control in boilers is based on maintaining the pH of boiler waters, typically in the pH range 9–10, by the addition, at the ppm level, of either free sodium hydroxide or combinations of sodium phosphates that buffer the pH in the required range but have the potential to release free sodium hydroxide, depending on the Na:P ratio. The concentration of these alkaline species can be increased by several orders of magnitude from the ppm to the percent level in films of boiler water on heat transfer surfaces when the metal skin temperature exceeds the boiling temperature of the water at the prevailing pressure. The driving force for concentration is related to the temperature difference between the two,  $\Delta T$ , as illustrated in **Figure 5**.<sup>11</sup>

Heat transfer into a crevice, as might exist at a tube/tubesheet joint in a boiler, can exacerbate the driving force for concentration.<sup>12</sup> These concentration processes at local sites in steam raising equipment can result in the on-load, caustic corrosion, sometimes described as ‘caustic gouging,’ of utility<sup>13</sup> and process plant<sup>14</sup> steel boiler tubes, and also give

rise to caustic-induced SCC of carbon, low alloy and stainless steels, and nickel alloy components, exemplified by the caustic cracking of a carbon steel stub attached to an alloy 825 (N08825) bellows that is illustrated in **Figure 6**. The root cause of the problem was a malfunctioning desuperheater upstream of the bellows that injected periodic slugs, rather than the

**Figure 5** Concentration of sodium hydroxide attainable in a film of boiler water on a heat transfer surface as a function of the temperature difference,  $\Delta T$ , between the surface temperature and the boiling point of the water. Adapted from *Betz Handbook of Industrial Water Conditioning*, 9th ed.; Betz Laboratories, 1991.

intended spray, of water containing a few ppm of sodium hydroxide into the pipe. The water collected in the crevice between the stub and the bellows and successive wetting/drying events resulted in concentration of the caustic in the crevice, leading ultimately to SCC of the stub, driven by the residual stresses around the attachment weld to the bellows.

Grey and ductile cast irons have corrosion resistances broadly similar to steels in sodium hydroxide. Ductile irons, in contrast to grey irons, are vulnerable to SCC. A comparative study of pure iron and white cast iron in 14 M ( $\sim 56\%$  w/w) acid in the temperature range 20–60°C suggested that iron carbide is detrimental to corrosion performance in relatively concentrated sodium hydroxide.<sup>15</sup> Nickel has the most significant influence on the corrosion resistance of cast irons, as shown by the corrosion rate data in **Figure 7** for cast irons with varying nickel contents in boiling 50–65% (w/w) sodium hydroxide.<sup>16</sup>

In particular, the austenitic irons containing >15% nickel (such as F41000, F41002, and F43000) have very good resistance to sodium hydroxide solutions of up to  $\sim 70\%$  (w/w) concentration, but can be vulnerable to SCC, particularly if chlorides are present, for which stress relief provides appropriate mitigation.<sup>5</sup> High silicon cast irons, containing typically 14–16% Si (such as F 47003), are not resistant to relatively concentrated sodium hydroxide at elevated temperatures because the siliceous films that provide their resistance to erosion–corrosion are soluble in the alkali.

**Figure 6** Section through carbon steel bellows stub downstream of a desuperheater in a steam main operating at  $\sim 16$  bar and 250°C that has suffered caustic SCC due to sequential wetting/drying in the crevice between the stub and the alloy 825 convolutions.

Although there is very little specific data in the public arena, the performances of steels and cast irons in potassium hydroxide are very similar to their equivalent performances in sodium hydroxide.

### 2.21.3 Stainless Steels

Potentiodynamic polarization curves in stagnant 15% (w/w) sodium hydroxide solution at 90 °C for the key constituent elements of stainless steels, pure

**Figure 7** Corrosion rates for cast irons containing varying quantities of nickel tested in boiling 50–65% (w/w) sodium hydroxide solution. Adapted from Corrosion Resistance of Nickel and Nickel-Containing Alloys in Caustic Soda and Other Alkalis; CEB-2, International Nickel Company, 1973.

iron, nickel, chromium, and molybdenum, are shown in **Figure 8**.<sup>17</sup> Iron has the most active corrosion potential, and in the early stages of anodic polarization, it dissolves at progressively increasing rates. At a relatively high, critical current density, it exhibits classic passivation behavior due to the formation of magnetite,  $\text{Fe}_3\text{O}_4$  which shows gradually increasing rates of dissolution as the potential is further increased to a secondary passivation peak, probably associated with the oxidation of  $\text{Fe}_3\text{O}_4$  to  $\text{Fe}_2\text{O}_3$ . The current density shows little tendency to increase in response to further polarization up to a potential >300 mV at which transpassive breakdown as soluble ferrate,  $\text{FeO}_4^{2-}$ , occurs.

Molybdenum has a corrosion potential more noble than iron but more active than chromium or nickel. However, under anodic polarization, molybdenum dissolves at progressively faster rates as soluble molybdate,  $\text{MoO}_4^{2-}$ , and shows no tendency to passivate. Chromium, on the other hand, has the most noble corrosion potential, and its initial anodic polarization behavior is consistent with the presence of a protective passive film of chromium oxide,  $\text{Cr}_2\text{O}_3$ , from the outset with no evidence of an active dissolution peak prior to the onset of passivity. When present, the film is more protective than the corresponding films on iron and nickel, having the lowest current density requirement for maintenance in its passive potential range. However, transpassive breakdown to soluble chromate,  $\text{CrO}_4^{2-}$ , occurs at a potential

**Figure 8** Potentiodynamic polarization curves for pure iron, nickel, chromium, and molybdenum in stagnant 15% (w/w) sodium hydroxide at 90 °C. Adapted from Bhattacharya, A.; Preet, M. S. In *Corrosion 2008, Corrosion of Duplex Stainless Steels in High pH Caustic Solution*, New Orleans, LA; NACE International: Houston, TX, 2008; Paper 08194.

well below the corresponding breakdown potentials for iron and nickel.

The corrosion potential of nickel is more noble than either iron or molybdenum but less noble than chromium. Nickel's anodic polarization behavior attests to the importance of the element in providing resistance to strongly alkaline environments. The critical current density for passivation is an order of magnitude lower than that for iron. The passive zone extends over a wide potential range within which nickel is protected by nickel oxide, NiO. As the potential increases in the passive range, the current density also increases gradually but the current densities for the maintenance of passivity are only marginally higher than for chromium. Ultimately, transpassive breakdown does occur at a similar potential in iron due to the formation of a soluble species, probably  $\text{HNO}_2 \cdot \text{H}_2\text{O}$ , well beyond the transpassive breakdown potential of chromium.

The polarization curves for the individual alloying elements explain their effects on the performances of stainless steels. The compositions of the commercial grades of stainless steels that are relevant to alkali applications are summarized in Table 1.

Nickel delivers the most significant benefits, providing additional resistance to anodic dissolution at lower potentials and robust passivity across a

potential range wide enough to limit the possible promotion of transpassivity by oxidizing agents. Chromium also delivers significant benefits by inhibiting dissolution and promoting passivity at lower potentials but introduces a vulnerability to transpassive dissolution in the presence of oxidizing agents. Molybdenum's benefits are confined to additional resistance to anodic dissolution in the active potential range.

These roles for the individual alloying elements are apparent in the formation of the passive films that form spontaneously on stainless steels in alkalis. Film formation was studied recently<sup>18</sup> in an X-ray photoelectron spectroscopic (XPS) study of the progressive formation of the naturally formed passive films on types 304 (S30400) and 2205 (S32205) stainless steel in 0.4% (w/w) sodium hydroxide solution at ambient temperatures, in which the natural corrosion potential of both increases with time. On first immersion, iron dissolves preferentially and is present in the film ultimately as  $\text{Fe}^{3+}$  oxy-hydroxide, the content of which decreases with time. Chromium accumulates with time in the film as  $\text{Cr}^{3+}$  oxy-hydroxide, and the combined effect of iron and chromium depletion is that the metal layer beneath the film becomes enriched in nickel, which accumulates in the film as nickel hydroxide, to a greater extent on

type 304 (S30400) than the 2205 (S32205) stainless steel. The molybdenum in the 2205 (S32205) stainless steel is present as an oxy-hydroxide in the film and in the metallic form at the metal/film interface at the same level as in the parent material. The dealloying effects are exacerbated in more aggressive conditions at higher temperatures and in more concentrated solutions to the extent that 'nickel' layers have been reported on austenitic stainless steel surfaces. It has been shown that, in reality, the dealloying of iron from the surface of type 316 stainless steel proceeds as far as a solid solution with a nickel/iron atomic ratio of  $\sim 1.3$ , equivalent to  $\sim 56\%$  nickel, in 50% (w/w) sodium hydroxide solution at  $140^\circ\text{C}$ .<sup>19</sup>

In practice, the relative contribution of chromium and nickel to the corrosion resistances of stainless steels in alkalis depends on and varies with the grade. The standard ferritic grades of stainless steel such as types 430 (S43000) and 439 (S43035), containing up to  $\sim 19\%$  chromium, do not find significant application in alkalis. However, the so-called super-ferritic grades containing typically 26–29% chromium with controlled carbon + nitrogen levels or stabilized with titanium or niobium to control vulnerability to intergranular corrosion due to sensitization, typified by the proprietary grades E-brite 26–1 (S44627) and AL 29–4C (S44735), have significant, potentially useful resistance. The corrosion rate data in Figure 9 demonstrate the superior performance of the super-ferritic grades relative to conventional austenitic grades of stainless steel in tests in 50% (w/w) sodium hydroxide at  $140^\circ\text{C}$  in which a conventional ferritic grade performed relatively badly.<sup>20</sup> Superferritic stainless steels have found commercial application as tubing materials

in caustic evaporators, and are not adversely affected to any significant extent by the presence of contaminants. Indeed, they require a sustained supply of oxidizing contaminants such as chlorates to maintain passivity at the prevailing high temperatures and concentrations.<sup>5</sup>

Isocorrosion diagrams for the basic types 304 (S30400) and 316 (S31600) austenitic stainless steels in sodium hydroxide are shown in Figure 10.<sup>21</sup> There is little to choose between the grades and their low carbon equivalents, all of which are resistant up to  $\sim 20\%$  (w/w) boiling sodium hydroxide solutions. Corrosion rates for some duplex stainless steels in boiling sodium hydroxide solutions are shown in Figure 11<sup>22</sup> and suggest that duplex alloys are resistant up to  $\sim 30\%$  (w/w) boiling sodium hydroxide solutions, depending on the chromium and nickel contents of the specific grade.

The corrosion rates of various grades of duplex stainless steels in 30–70% (w/w) sodium hydroxide solutions are in the order S32906 < 2507 (S32750) < 2205 (S32205) < 2304 (S32304), confirming that their resistances are determined largely, but not exclusively, by their chromium contents.<sup>23</sup> However, the vulnerability of chromium to transpassive dissolution was confirmed in studies of austenitic and duplex alloys in 30% (w/w) sodium hydroxide at  $150^\circ\text{C}$ . Under deaerated conditions, the strong, passivating effects of both chromium and nickel were confirmed. However, in more strongly oxidizing conditions, chromium was dissolved resulting in thicker, less protective oxide films containing only nickel and iron.<sup>24</sup>

The overall effects of additions of the major alloying elements nickel, chromium, and molybdenum on the corrosion of austenitic and duplex stainless steels

year<sup>-1</sup> for the grades 304 (S30400), 316L (S31603), 2205 (S32205), 2304 (S32304), 2507 (S32750), 254SMO (S31254), 654SMO (S32654), and 904L (N08904).<sup>5</sup>

The most significant alloying element is clearly nickel, with both chromium and molybdenum demonstrating only minor benefits within the relevant composition ranges. The beneficial effects of nickel additions were demonstrated in a study of stainless steels and nickel alloys in 50% (w/w) sodium hydroxide at 300 °C in the presence and absence of oxygen, the results of which are shown in Figure 13.<sup>25</sup> Clearly, corrosion rates are very sensitive to the presence or otherwise of oxygen but in all conditions, the resistance increases with nickel addition up to a content of ~20%, but not beyond under these relatively aggressive conditions.

At lower temperatures, alloys with >20% nickel such as 904L (N08904) and alloys 20 (N08020), 800 (N08800), and 33 (R20033) provide much improved resistance to sodium hydroxide relative to the basic austenitic grades and cheaper alternatives to nickel based alloys. For example, Figure 14 shows corrosion rates for alloy 33 relative to nickel alloys 600 (N06600) and 625 (N06625) in 50% (w/w) sodium hydroxide solution at 180 °C. Although not as resistant as alloy 600 (N06600), alloy 33 (R20033) corrodes at a rate of <0.1 mm year<sup>-1</sup> that is acceptable for most applications and is much more resistant than the molybdenum-containing alloy 625 (N06625). Additionally, alloy 33 (R20033) shows no evidence of dealloying after 153 days exposure, in contrast to

**Figure 13** Effect of nickel content on the corrosion rates of stainless steels and nickel alloys in 50% (w/w) sodium hydroxide at 300 °C in the presence and absence of oxygen. Adapted from Yasuda, M.; Fukumoto, K.; Koizumi, H.; Ogata, Y.; Hine, F. *Corrosion* **1987**, 43, 492–498.

**Figure 14** Corrosion rates and dealloyed layer thicknesses for alloys 600, 625 and 33 tested in 50% (w/w) sodium hydroxide solution at 180 °C. both of the nickel alloys that are significantly dealloyed after 35 days exposure.<sup>26</sup>

Stainless steels are vulnerable to SCC in alkaline solutions. It has been proposed that the vulnerability is due to the iron and chromium dealloying processes that occur on stainless steel surfaces in alkaline exposures<sup>19</sup> and this is described in more detail in **Chapter 2.05, Dealloying** in this volume. The conditions of concentration and temperature that present risks to the basic types 304 (S30400) and 316 (S31600) austenitic stainless steels are shown in **Figure 9** which confirms that SCC is possible at temperatures above ~100 °C, depending on concentration. Tests on duplex stainless steels have revealed no evidence of SCC in boiling 20–70% (w/w) solutions, suggesting that they are at least as resistant as the basic austenitic grades.<sup>21,23</sup> Various studies have indicated that chromium is more important than nickel in determining the resistance to SCC in alkaline solutions. For example, in 30% (w/w) sodium hydroxide at 200 °C, the resistances to cracking in separate studies were in the order 2205 (S32205) > 316L (S31603) > 904L (N08904) and 33 (R20033) > 28 (N08028) > 825 (N08825) > 904L (N08904).<sup>27,28</sup>

Overall, contaminants do not appear to have any significant adverse effects on either the corrosion rates or the vulnerability to SCC of stainless steels in sodium hydroxide solutions. The oxidizing chlorates at the normal levels of contamination appear to be beneficial toward stainless steels in helping to promote and sustain passivity. There is no evidence that SCC risks are exacerbated in sodium hydroxide solutions by the presence of chlorides up to their maximum contaminant levels. However, if the sodium hydroxide is neutralized, the risks of chloride-induced SCC are reintroduced.

Although there is very little specific data in the public arena, the performances of stainless steels in potassium hydroxide are broadly similar to their equivalent performances in sodium hydroxide. A specific study of type 304L (S30403) austenitic stainless steel showed potassium hydroxide to be less aggressive than sodium hydroxide in promoting caustic-induced SCC.<sup>29</sup>

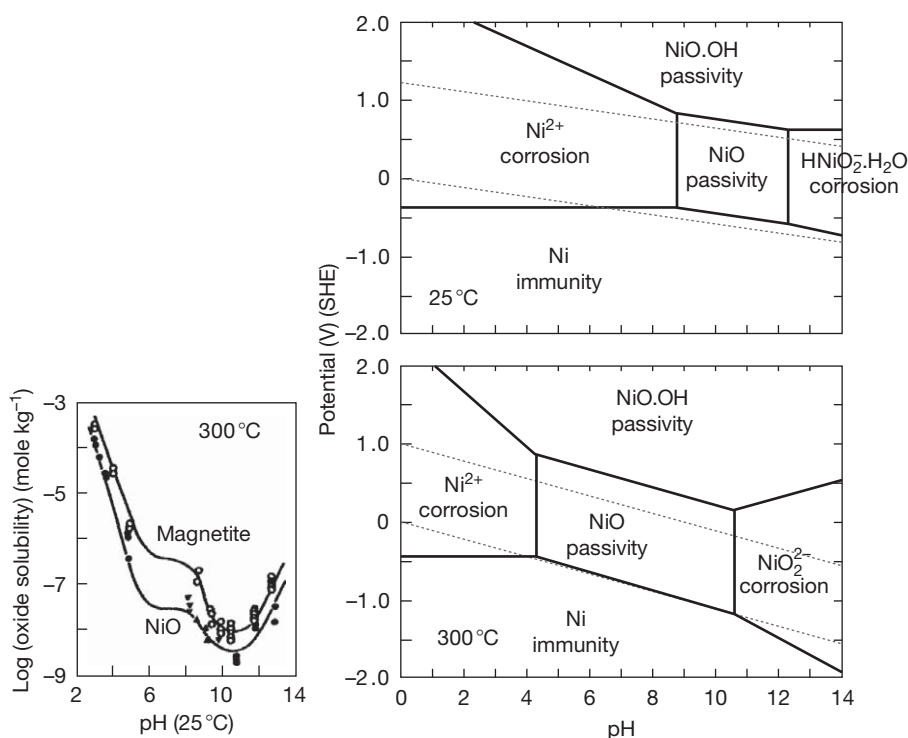

## 2.21.4 Nickel and Nickel Alloys

The compositions of the commercial nickel alloys that are relevant to alkali applications are summarized in **Table 2**. Nickel is second only to silver in its resistance to concentrated alkalis at elevated

**Figure 15** Simplified potential/pH diagrams for the Ni-H<sub>2</sub>O system at 25 °C and 300 °C, based on an equilibrium activity of 10<sup>-5</sup> molal, calculations performed using HSC Chemistry V6.12, Outotec Research, Finland. Oxide solubility data adapted from Turnbull, A.; Psaila-Dombrowski, M. *Corros. Sci* **1992**, 33, 1925–1966.

temperatures where nickel and its alloys find significant commercial application. The temperature range up to ~300 °C is of particular significance because evaporator tubes that are used for the commercial manufacture of 73% (w/w) sodium hydroxide and steam generator tubes in pressurized water reactors (PWR) in the nuclear industry both operate at

~300 °C. The basis of the good performance of nickel and its alloys under these conditions is the formation and maintenance of highly insoluble, nickel oxide, NiO, films. The Pourbaix diagrams for the nickel-water system shown in Figure 15 confirm the existence of the NiO passivation zone and define its thermodynamic boundaries at 25 °C and 300 °C.

Despite the apparent threat to passivity due to the encroachment of corrosion zones based on the formations of soluble  $\text{H}\text{NiO}_2 \cdot \text{H}_2\text{O}$  and  $\text{NiO}_2^-$  at 25 °C and 300 °C respectively, in practice a kinetic passivation zone extends much further into the alkaline pH region. The passive film forms much more rapidly than it dissolves because of the low solubility of NiO, exemplified by the comparative data for magnetite and NiO at 300 °C<sup>30</sup> that is also shown in Figure 15. In practice, both of the commercial purity grades of nickel, 200 (N02200) and 201 (N02201), have excellent resistance to sodium hydroxide across wide ranges of concentration and temperature, as shown in Figure 16, and find significant application in caustic evaporation equipment. The low carbon grade 201 is generally preferred for service above 300 °C to avoid problems associated with loss of ductility and intergranular attack due to the precipitation of graphite in the alloy.

However, the corrosion rates of commercially pure nickel are very sensitive to the presence and concentration of oxidizing chlorates and hypochlorites that have a significant influence on the life of caustic evaporation equipment. The test results in Figure 17 are corrosion rates for a duplex stainless steel (S32906) and nickel 200 (N02200) in boiling 50% (w/w) sodium hydroxide solution with different

**Figure 16** Isocorrosion diagram for nickel 200 and low carbon nickel 201 in sodium hydroxide. Adapted from Corrosion Resistance of Nickel and Nickel-Containing Alloys in Caustic Soda and Other Alkalies; CEB-2, International Nickel Company, 1973.

levels of chloride and chlorate contaminants. The differing effects of oxidizing contaminants on stainless steels and nickel are apparent.

The chromium-free nickel alloys that find significant applications in sodium hydroxide, particularly in evaporation equipment, are the nickel copper alloys 400 (N04400) and 500 (N05500) that have equivalent corrosion resistance to sodium hydroxide up to ~73% (w/w) concentration. However, in keeping with nickel 200 (N02200) and 201 (N02201), their corrosion resistance is very sensitive to the presence of oxidizing agents such as chlorates and hypochlorites that have to be controlled below threshold levels to avoid excessive corrosion and contamination of the product sodium hydroxide with nickel and copper corrosion products.<sup>5,31</sup> The alloys 400 (N04400) and 500 (N05500) are also vulnerable to caustic-induced SCC and liquid metal embrittlement (LME) by mercury in the case of components that handle mercury cell caustic prior to final separation of mercury and its salts from the product caustic.<sup>21</sup> The chromium-free B family of alloys also has good resistance to sodium hydroxide in the absence of oxidizing agents but the advantages they offer over cheaper alternatives are marginal and they have found little application.

The preferred chromium-bearing alloy for sodium hydroxide applications at higher temperatures is alloy 600 (N06600) that has comparable, arguably better, resistance to corrosion than the commercially pure nickel alloys exemplified by the corrosion rates in boiling solutions for the two materials that are shown in Figure 18.<sup>5</sup>

Alloy 600 (N06600) has two additional advantages over commercially pure nickel. It is more resistant to

**Figure 17** Corrosion rates for a duplex stainless steel and nickel 200 in boiling 50% (w/w) sodium hydroxide solution with different levels of chloride and chlorate contaminants. Adapted from Leander, D. Corrosion Characteristics of Different Stainless Steels, Austenitic and Duplex, in NaOH Environments Stainless Steel World Conference Maastricht, Stainless Steel World, 2003.

the presence of sulfur-containing contaminants in the sodium hydroxide that can promote intergranular penetration of nickel due to the formation of a low melting point nickel/nickel sulfide eutectic. It is also more tolerant to the presence of oxidizing agents such as chlorate and hypochlorite due to the passivation reinforcing effects of the chromium in the base metal. However, on the downside, the alloy 600 (N06600) is vulnerable to caustic-induced SCC at temperatures above  $\sim 190^\circ\text{C}$  in concentrated sodium hydroxide. In principle, the risk of SCC can be mitigated by appropriate thermal stress relief but this requires exposure to relatively high temperatures for significant time periods (for example,  $\sim 900^\circ\text{C}$  for 1 h) and is not always practicable for complex equipment items.

Few corrosion problems have been studied as intensively as the SCC vulnerability of alloy 600 (N06600) that has been used extensively as a steam generator tube material in PWRs in the nuclear industry. This is a complex topic that is described in more detail elsewhere<sup>32</sup> and in **Chapter 2.09, Stress Corrosion Cracking** in this volume. The research has included detailed investigations of the intergranular cracking (IGSCC) of alloy 600 (N06600) in concentrations of  $\sim 10\%$  (w/w) sodium hydroxide at  $\sim 300^\circ\text{C}$ . The IGSCC occurs in a relatively narrow band of corrosion potentials close to the Ni/NiO equilibrium that are adopted by the alloy in the deaerated boiler water. Carbon content and carbide morphology play an important role. Intergranular carbides improve

IGSCC resistance, and heat treatments for alloy 600 that develop preferred microstructures have been proposed and adopted. Operating experience has established that alloys 800 (N08800) and 690 (N06690) are much more resistant to IGSCC than alloy 600 (N06600). Recently, it has been proposed that internal, intergranular oxidation of chromium is the initiating process for IGSCC in alloy 600 (N06600). In contrast, alloy 690 (N06690) resists IGSCC because its much higher chromium content allows it to form a protective external oxide, and alloy 800 (N08800) has sufficient nickel to resist the dealloying processes that might render it vulnerable to the mechanism for caustic-induced SCC in stainless steels and sufficient chromium to form an external oxide and resist the internal oxidation route to crack initiation.<sup>33,34</sup>

The nickel–chromium–molybdenum alloys such as alloys 625 (N06625), 59 (N06059), and the C family do not find significant application in alkalis because, at the margin, they are less resistant than other nickel based alloys and in conditions where they have useful resistance, there are cheaper alternatives.

The corrosion rates shown in **Figure 19** for various nickel alloys in 70% (w/w) sodium hydroxide solution at  $170^\circ\text{C}$ <sup>35</sup> confirm that the two nickel–chromium–molybdenum alloys are outperformed by the nickel–copper and nickel–chromium–iron alloys. The nickel–chromium–molybdenum alloys are also vulnerable to caustic-induced SCC.<sup>36</sup> Arguably, the nickel–chromium–molybdenum alloys might be more tolerant to the presence of oxidizing agents such as chlorates and hypochlorites, but this has to be offset against the vulnerability of molybdenum to transpassive dissolution in alkaline media. In practice,

**Figure 18** Corrosion rates of alloys 201 and 600 in boiling 50% (w/w) sodium hydroxide solution. Adapted from Davies, M. *Corrosion by Alkalies*. In *ASM Handbook: Corrosion: Environments and Industries*; ASM International: Materials Park, OH, 2006; Vol. 13C, pp 710–726.

**Figure 19** Corrosion rates for various nickel alloys in 70% (w/w) sodium hydroxide solution at  $170^\circ\text{C}$ . Adapted from Heubner, U.; Kohler, M. *High Alloy Materials for Aggressive Environments*; ThyssenKrupp VDM GmbH 1998; VDM Report No 26.

the nickel–chromium–molybdenum alloys are specified only when their corrosion resistance to other fluids are required simultaneously, such as in heat exchange duties for alkaline fluids where the heating or cooling fluid is sufficiently corrosive as to require a nickel–chromium–molybdenum alloy.

Although there is very little specific data in the public arena, the performances of nickel alloys stainless steels in potassium hydroxide are broadly similar to their equivalent performances in sodium hydroxide.

## 2.21.5 Other Metals and Alloys

Commercial purity zirconium (Zr702, R60702) is protected by a surface oxide film, composed mainly of  $\text{ZrO}_2$ , that is extremely resistant to alkaline attack, as a result of which zirconium has excellent resistance to alkalis, both aqueous and fused. Thus, it resists 73% (w/w) sodium hydroxide up to 138 °C and molten sodium hydroxide at temperatures above 1000 °C. It is resistant to the presence of oxidizing contaminants unless significant amounts of chlorides are present. It is resistant to SCC in boiling solutions but is very vulnerable to LME if contaminant mercury is present.<sup>5</sup> More detailed information is given in **Chapter 3.14, Corrosion of Zirconium and its Alloys**.

Titanium and its alloys are also dependent on the formation of protective oxide films consisting mostly of titanium dioxide,  $\text{TiO}_2$ , for their resistances to corrosion. However, the  $\text{TiO}_2$  film on titanium is more soluble in alkaline conditions than the equivalent  $\text{ZrO}_2$  film on zirconium. In practice, commercially pure titanium (ASTM grade 2, R50400) is resistant over a wide range of concentrations at ambient temperatures but increases in temperature increase the film dissolution rate. Titanium's performance limits are determined as much by vulnerability to the hydriding caused by the hydrogen released in the corrosion process as by the corrosion rate *per se* that might otherwise be acceptable. Hydrogen absorption is particularly prevalent in the 20–40% (w/w) concentration range and at 50% (w/w) sodium hydroxide, the temperature has to be limited to ~80 °C to avoid excessive hydriding and embrittlement.<sup>37</sup>

Copper piping has been used for handling sodium hydroxide solutions in the absence of oxidizing agents and tolerates temperatures up to ~100 °C at 73% (w/w) concentration. The cupronickels (grades 90–10, C70600 and 70–30, C71500) have improved resistance and have found application in caustic evaporation up to 50% (w/w) concentration if some

copper contamination is acceptable.<sup>5</sup> However, copper contamination is not acceptable in several major uses of the sodium hydroxide product and this inevitably limits the usage of copper and its alloys in alkaline applications.

Silver has exceptional resistance to sodium hydroxide at temperatures well beyond boiling but its cost precludes other than niche use. The amphoteric metals are clearly precluded from significant application, and tantalum has very poor resistance to caustic solutions and finds no application.

## 2.21.6 Nonmetallic Materials

### 2.21.6.1 Thermoplastic and Reinforced Thermosetting Materials

In practice, chemical compatibility is, but, one factor that determines the suitability or otherwise of a thermoplastic material for a specific application. Other factors such as mechanical and fabrication properties, thermal expansion characteristics, permeation properties, etc. are significant design considerations. In practice, other than for small scale equipment, thermoplastics are used more commonly as linings on stronger substrates rather than in solid form, because of reliability and integrity concerns. The application of these materials is covered in more detail in the relevant chapters in this book but the more significant materials are as follows:

1. Polyethylene (PE) and polypropylene (PP) have good resistance. High density polyethylene (HDPE) and PP resist concentrations up to ~70% (w/w) at temperatures up to ~60 °C and ~100 °C respectively.
2. Polyvinyl chloride (PVC) resists concentrations up to ~70% (w/w) at temperatures up to ~40 °C, although PVC-lined fiber reinforced plastic (FRP) construction is generally preferred to solid PVC on safety grounds. Chlorinated polyvinyl chloride (CPVC) tolerates higher temperatures.
3. Fluoroplastics are very resistant to alkaline solutions, depending upon their degree of fluorination. The highly fluorinated materials polytetrafluoroethylene (PTFE), fluorinated ethylene propylene (FEP), and perfluoroalkoxy (PFA) resist concentrations up to ~70% (w/w) at temperatures up to 150 °C and beyond. The less highly fluorinated materials ethylene chlorotrifluoroethylene (ECTFE), ethylene tetrafluoroethylene (ETFE), and polyvinylidene fluoride (PVDF) are also very resistant but have lower temperature limits for service than the fully fluorinated grades.

FRP constructions can be used, but the common isophthalate and phenolic resins are not resistant to, and glass is attacked by, caustic solutions. FRP construction is therefore based on the use of specific resins such as epoxy, bisphenol-A fumarate, and vinyl ester resins and special surfacing veils of materials such as polyesters and acrylics. Dual laminate construction is also common, involving the use of resistant, thermoplastic liners supported by FRP. Materials selection needs care and experience, and suppliers should always be consulted in the selection of thermoplastic or thermosetting construction for caustic applications.

### 2.21.6.2 Elastomers

Natural rubber is resistant to concentrations up to 70% (w/w) at temperatures up to  $\sim 60^{\circ}\text{C}$ , and in the case of hard natural rubber up to temperatures as high as  $\sim 90^{\circ}\text{C}$ . Several synthetic rubbers, including chlorosulfonated PE (such as Hypalon), butyl, nitrile butadiene, and butadiene rubbers also have good resistance up to  $\sim 60^{\circ}\text{C}$  and beyond. Silicone and polysulfide rubbers are restricted to temperatures close to ambient.

### 2.21.6.3 Inorganic Materials

Impervious graphite finds application depending on the impregnant. Of the common impregnants, carbon tolerates up to 80% (w/w) concentration at temperatures up to  $\sim 80^{\circ}\text{C}$ . The PTFE impregnant is also tolerant to relatively demanding conditions, but phenolic resins are limited to much lower concentrations and are substituted with furane resins for more demanding applications.

Ceramics find only limited application. Borosilicate glass is very restricted in the concentrations and temperatures that it can handle, and glass linings are restricted essentially to dilute solutions at low temperatures.

### 2.22.1 Introduction

The hydrohalic acids comprise the group of monobasic acids that are formed when the hydrogen halide gases are dissolved in water, with strengths in descending order:

hydroiodic (HI) > hydrobromic (HBr) > hydrochloric (HCl) > hydrofluoric (HF)

The differences in strength arise from the differing sizes of the relevant halide ion. Thus, the largest iodide anion interacts relatively weakly with its complementary proton, leaving it relatively free to dissociate. In practice, the differences amongst HI, HBr, and HCl acids are not great, and all are strong acids that are highly dissociated in water at all concentrations to

release protons and the corresponding halide anion as follows:

The result, in relation to the pHs of hydrohalic acids, is that at the higher end of the pH range the solutions are effectively acidified waters. Thus, the pHs 2, 3, and 4 are equivalent to concentrations of 360, 36, and 3.6 ppm (w/w) hydrochloric acid, respectively at 25 °C. However, HF acid is an exception to this behavior. There is very strong hydrogen bonding between the nonionized HF and water molecules, and the small fluoride anion imposes a high degree of order on the surrounding protons and water molecules as a result of which HF acid is a very weak acid, the pH of which varies in a complicated manner with concentration as shown in Figure 1.<sup>1</sup>

Hydrogen chloride, bromide, and iodide are all gases at ambient temperatures and available commercially in nominally anhydrous specifications, containing trace quantities of water. Anhydrous hydrogen fluoride (AHF) is a liquid that boils at ~20 °C, and is normally specified as containing < 400 ppm water. The significant commercial grades of the acids are as follows:

1. HI acid, the least significant acid commercially, is supplied at various concentrations, typically 47% or 55% (w/w), but concentrated grades in the range 90–98% (w/w) are also available.
2. Hydrobromic acid is manufactured in significant quantities and supplied at various concentrations, most commonly at ~47–49% (w/w).
3. Hydrochloric acid is manufactured in the greatest quantities at concentrations up to ~38% (w/w), above which the fuming nature of the acid

**Figure 1** pH of hydrofluoric acid solutions. Adapted from *Hydrofluoric Acid Properties*; Honeywell Specialty Materials Products, 2002.

introduces problems in relation to storage and transport. Most bulk commercial grades have concentrations in the range 30–35% (w/w).

4. HF acid is also significant commercially, and is available in bulk at concentrations of 49% and 70% (w/w).

From the corrosion standpoint, the hydrohalic acids are commonly classified as inherently ‘reducing’ acids because the only cathodic process that the pure acids can deliver is the reduction of protons to evolve hydrogen:

This is in contrast to ‘oxidizing’ acids such as sulfuric and nitric acid in which reductions of the acid itself, or its constituent species, occur at potentials more noble than hydrogen evolution, and to an extent that can determine the behaviors of materials exposed to the acid, as described in the separate chapters devoted to the two acids in this book. In the case of the hydrohalic acids, their ‘reducing’ characteristics are compounded by the aggressive properties of the halide anions that inhibit the formation of, and attack preexisting, protective passive layers on metals and alloys. Indeed, both HCl and HF acids find significant commercial applications in the cleaning and pickling of metals and alloys because of their ability to dissolve metal oxides.

In practice, alternative cathodic processes to hydrogen evolution may be available due to the presence of specific contaminants in the acid, in particular oxidants such as dissolved oxygen and metal cations in a higher oxidation state such as ferric,  $\text{Fe}^{3+}$  or cupric,  $\text{Cu}^{2+}$  ions. The presence of the corresponding halogen gas, for example chlorine in the case of hydrochloric acid, can also have a significant effect. The effects of oxidizing agents that raise the potentials of metals and alloys are almost invariably detrimental to corrosion performance in the hydrohalic acids, in which metals and alloys are mostly unable or struggle to form protective, passive films, as will emerge below.

The corrosion performances of the various classes of material in hydrohalic acids have been reviewed extensively elsewhere.<sup>2–8</sup> Much of the data relate to hydrochloric and HF acids, reflecting their commercial significance. There is relatively little data for hydrobromic, and virtually none for HI acid in the public domain. Readers whose main interest is to identify ‘what works where’ are referred to these sources and the relevant chapters on specific materials in this book. In this chapter, the corrosion

**Figure 2** Proposed design limits for various alloys in anhydrous hydrogen chloride. Adapted from Schillmoller, C. M. *Chem. Eng.* **1980**, 87, 161–163.

performances of materials are reviewed with an emphasis on the principles and mechanisms that underpin their corrosion performances in the acids.

### 2.22.2 Steels and Cast Irons

Steels react with anhydrous hydrogen halide gases to form the corresponding iron halide and hydrogen. In AHF, the fluoride films are protective and steels have acceptable corrosion rates at temperatures up to  $\sim 200^\circ\text{C}$  and velocities up to  $10\text{ m s}^{-1}$ , and arguably to higher temperatures at lower velocities.<sup>3,6</sup> The velocity limitations arise because the fluoride films are vulnerable to detachment which not only increases the corrosion rates, but also adversely affects the operability of equipment due to accumulations of solid iron fluoride in seals and joints in valves, pumps, and elsewhere. In anhydrous hydrogen chloride gas, the growth of a film of  $\text{FeCl}_2$  obeys parabolic kinetics up to temperatures of  $500\text{--}600^\circ\text{C}$ , above which the vaporization of  $\text{FeCl}_2$  results in a switch to linear, nonprotective kinetics. As in the case of the analogous fluoride films, the chloride films on steels are protective within specific temperature and velocity constraints,<sup>5,9,10</sup> and some widely used design temperature limits for carbon steel, austenitic stainless steels, and specific nickel alloys in anhydrous hydrogen chloride are shown in **Figure 2**.<sup>10</sup>

Aqueous hydrohalic acids are very aggressive toward steels and grey or ductile cast irons. A typical polarization curve for carbon steel in stagnant, aqueous 3M ( $\sim 10\%$ , w/w) hydrochloric acid is shown in **Figure 3**.

**Figure 3** Potentiodynamic polarization curve for carbon steel in stagnant, 3M ( $\sim 10\%$ , w/w) hydrochloric acid open to air at ambient temperature. Adapted from Poorqasemi, E.; Abootalemi, O.; Peikari, M.; Haqdar, F. *Corros. Sci.* **2009**, 51, 1043–1054.

The anodic curve shows classic Tafel behavior, characteristic of active dissolution of iron:

The cathodic curve also shows classic Tafel behavior, characteristic of hydrogen evolution. In more dilute acids, curves are obtained that are time dependent to a small extent, and electrochemical impedance spectroscopic (EIS) measurements suggest the presence of highly nonprotective films that present limited

barriers to anodic dissolution.<sup>11</sup> Such films that do exist are likely to consist of iron chloride, which is very soluble in hydrochloric acid and the degree of protection that they can provide is therefore very marginal. The general experience of steels in aqueous HCl, HBr, and HI acids is of active corrosion across the full concentration range at rates that preclude practical application.

In aqueous HF acid, corrosion rates are generally lower, but acceptable only at concentrations above ~70% (w/w), as shown in Figure 4. The corrosion resistance of steels in concentrated aqueous and liquid AHF arises from the spontaneous formation of protective iron fluoride films on steel surfaces that are much less soluble than the corresponding chloride films. Studies of the growth of fluoride films in vapors over dilute HF acids at ambient temperature have shown that the kinetics is linear, and controlled by reaction at the metal–film interface, resulting in the formation of porous, nonprotective films. However, when the HF acid concentration rises to 40% (w/w), the initial film that forms in the vapor phase has been identified as  $\text{FeF}_2 \cdot 4\text{H}_2\text{O}$ , and it grows with a parabolic dependence on time. With increasing film thickness, a product identified as nonstoichiometric  $\text{Fe}_2\text{F}_5 \cdot 7\text{H}_2\text{O}$  occurs. The change to parabolic kinetics indicates a switch to diffusion control of reaction rate through a thickening, potentially protective film.<sup>12</sup>

The significance of such films is evident in the polarization curves for two steels in 90% (w/w) acid at 90 °C, shown in Figure 5.

**Figure 4** Corrosion rate of carbon steel in hydrofluoric acid at 21–38 °C as a function of concentration. Adapted from NACE International Publication 5A–171 *Materials for Storing and Handling Commercial Grades of Aqueous Hydrofluoric Acid and Anhydrous Hydrogen Fluoride*; NACE International: Houston, TX, 2007.

In both cases, the anodic kinetics is clearly influenced strongly by diffusion due to the presence of the fluoride film, while the cathodic reactions obey Tafel-type kinetics, characteristic of hydrogen evolution beneath the film.<sup>13</sup> The adherence and protection afforded by the fluoride film has been shown to depend upon several factors. Although the laboratory test in Figure 5 demonstrates the existence of a film at 90 °C, temperatures and limiting velocities are typically restricted to ~65 °C and  $\sim 1.6 \text{ m s}^{-1}$  in liquid AHF, reducing to ~30 °C and  $0.6 \text{ m s}^{-1}$  in 70% (w/w) acid.<sup>6</sup> The carbon and residual element content of the steel, in particular the copper and nickel contents, also appear to influence the persistence of the fluoride films that form and the corresponding corrosion rates that are experienced,<sup>13</sup> and recommendations have been formulated relating to the control of such elements.<sup>14</sup> Corrosion rates have also been shown to be higher in the presence of oxygen in both the laboratory<sup>10</sup> and in the field.<sup>6</sup>

Steels are vulnerable to damage due to hydrogen uptake in HF acid service that is similar to the types of damage that can be experienced in wet  $\text{H}_2\text{S}$  such as hydrogen stress cracking (HSC) of stronger materials and hard welds and heat affected zones (HAZ), and hydrogen-induced cracking (HIC), stress-oriented hydrogen-induced cracking (SOHIC), and blistering of plate materials. General approaches to mitigating these risks are available<sup>7,15</sup> based on the

**Figure 5** Potentiodynamic polarization curves for steels in 90% (w/w) hydrofluoric acid at 90 °C. Adapted from Chirinos, G.; Turgoose, S.; Newman, R. C. *Effects of Residual Elements on the Corrosion of Steels in HF*, Paper 97513, Corrosion '97; NACE International: Houston, TX, 1997.

practices that have been developed for the control of the similar problems that are experienced in wet  $\text{H}_2\text{S}$ , including the control of base metal chemistry and the hardness of welds and HAZs within threshold levels and, if appropriate, postweld heat treatment (PWHT).<sup>16</sup> The risks of HIC and SOHIC in the base materials are mitigated by controlling steel chemistry and microstructure (including limits on sulfur content and inclusion shape control) and manufacture (in particular rolling conditions), and confirming resistance by appropriate testing.<sup>17–19</sup>

Gray and ductile cast irons have corrosion resistances broadly similar to steels in hydrohalic acids, but find no application in HF acid service, not least in the case of gray irons because of safety concerns relating to their poor ductility. High-silicon cast irons, containing typically 14–16% Si, are resistant to all concentrations of hydrochloric acid up to 40% (w/w) at ambient temperatures and at higher temperatures in more dilute acids, as shown in the isocorrosion curves for some metals and alloys with exceptional corrosion resistance to aqueous hydrochloric acid, described later in Figure 14. Their exceptional corrosion resistance is due to the formation of robust, siliceous films that have considerable resistance to erosion and abrasion. However, they find relatively limited application due to their poor ductility that renders them difficult to fabricate and requires them to be protected from thermal and/or mechanical shock.

### 2.22.3 Stainless Steels

The compositions of the relevant commercial grades of stainless steels are summarized in Table 1.

In anhydrous hydrogen chloride gas, stainless steels perform in a similar manner to steels in that they form chloride films that obey parabolic kinetics up to temperatures of 500–600 °C, above which the vaporization of the chlorides results in a switch to linear kinetics. However, the films contain  $\text{CrCl}_3$  and  $\text{NiCl}_2$  in addition to, or instead of  $\text{FeCl}_2$ , depending on the alloy and the temperature.<sup>10</sup> They form more slowly and are much more protective than the corresponding films on steels at temperatures below ~500 °C. As a result, the corrosion rates for stainless steels are lower than for steels, and the design temperature limits are correspondingly higher, exemplified by those reported in Figure 2.<sup>10</sup> At temperatures above ~500 °C, stainless steels offer no significant advantage over carbon or low alloy steels in anhydrous hydrogen chloride gas.

The performances of austenitic stainless steels in AHF liquid and vapor are good up to a temperature of ~100 °C. All of the basic grades 304 (S30400), 304L (S30403), 316 (S31600) and 316L (S31603), and their cast equivalents show good resistance and find significant application, although due caution to prevailing velocities is necessary as in the case of steels. However, austenitic stainless steels that can develop  $\alpha$ -martensite as a result of cold working are vulnerable

to HSC, and some users favor the higher nickel 316/316L grades for this reason.<sup>8</sup> Above  $\sim 100^\circ\text{C}$ , the rates of corrosion of austenitic stainless steels in AHF increase to unacceptable levels and they are outperformed by carbon steel, as shown in **Figure 6**.

The performances of stainless steels in aqueous hydrohalic acids are generally poor because they are unable to form and sustain the passive, chromium oxide films upon which they depend for corrosion resistance and, as a result, corrode actively. Ferritic and martensitic stainless steels have poor resistance under all conditions. Austenitic and duplex stainless steels offer some limited resistance, as shown in the isocorrosion diagrams for various grades in HCl and HF acids in **Figures 7 and 8** respectively.

The basic 316L (S31600) grade is clearly limited to very dilute acids at relatively low temperatures. The grades with higher levels of nickel, molybdenum, and copper offer progressive extension of the boundaries for stable passivity, but more than 30% nickel and significant contents of molybdenum and copper are required to provide resistance to hydrochloric acid at all concentrations up to 40% (w/w) at close to ambient temperatures, exemplified by the isocorrosion diagram for alloy 31 (N08031) which is shown in **Figure 9**.<sup>20</sup>

Overall, taking into account the additional risks of localized corrosion and stress corrosion cracking (SCC) presented by the halide anions, stainless steels are weak options for aqueous, hydrohalic acid service.

**Figure 6** Corrosion rates of carbon steel and type 304 stainless steel as a function of temperature in static, anhydrous hydrofluoric acid. Adapted from Jennings, H. S. *Corrosion by Hydrogen Fluoride and Hydrofluoric Acid*. In *ASM Handbook Corrosion: Environments and Industries*; ASM International, 2006; pp 690–703, Vol. 13C.

## 2.22.4 Nickel and Nickel Alloys

The compositions of the relevant commercial grades of nickel and its alloys are summarized in **Table 2**.

The reaction of nickel with anhydrous hydrogen chloride gas as a function of temperature is shown in **Figure 10**.<sup>21</sup>

Evidently, reaction kinetics is parabolic up to a temperature of  $\sim 450^\circ\text{C}$ , associated with the formation of protective  $\text{NiCl}_2$ . In the temperature range of  $450\text{--}550^\circ\text{C}$ , there is a transition to linear kinetics associated with the relatively high vapor pressure and progressive evaporation of  $\text{NiCl}_2$ . Alloying, in general, reduces the temperature at which there is a transition to unacceptable evaporation rates. The effects are relatively small for the commercial nickel–chromium

**Figure 7** Isocorrosion charts ( $0.1\text{ mm year}^{-1}$ ) for austenitic and duplex stainless steels in hydrochloric acid. Adapted from *Corrosion Handbook, Stainless Steels*; AB Sandvik Steel, 1994.

**Figure 8** Isocorrosion charts ( $0.1\text{ mm year}^{-1}$ ) for austenitic stainless steels in hydrofluoric acid. Adapted from *Corrosion Handbook, Stainless Steels*; AB Sandvik Steel, 1994.

and nickel–chromium–molybdenum alloys, but more significant for nickel–molybdenum and particularly nickel–copper alloys because of the relatively low melting point and high volatility of copper chloride. This is reflected in the relatively high, proposed, design temperature limits proposed in **Figure 2** for nickel 200 (N02200) and alloy 600 (N06600) compared with alloy 400 (N04400) for which the proposed limits are little better than those for carbon steel.<sup>10</sup>

The resistance of nickel and its alloys to AHF gas at elevated temperatures is dependent on the formation

**Figure 9** Isocorrosion chart ( $0.13 \text{ mm year}^{-1}$ ) for austenitic alloy 31 in hydrochloric acid. Adapted from Agarwal, D. C., Alves, H. *Applications of Alloys 59 (UNS N06059) and 31 (UNS N08031) in Mitigating Corrosion Risks in the CPI and Petrochemical Industries*, Paper 07186, Corrosion 2007; NACE International: Houston, TX, 2007.

of protective metal fluoride films. Nickel and molybdenum fluorides are stable and protective relative to chromium and iron fluorides that have lower melting points and higher volatilities, and this is reflected in the corrosion rates for various metals and alloys in AHF at  $600^\circ\text{C}$  that are charted in **Figure 11**<sup>22</sup> which links to the data reported in **Figure 6**.

Alloys can suffer internal as well as external attack in high temperature hydrogen fluoride related to fluoride diffusivity and solubility in the metal and, in addition to chromium and iron, the elements niobium, tantalum, and titanium also exacerbate the vulnerability of an alloy to internal attack due to the lower melting points and higher volatilities of their fluorides. **Figure 11** confirms that the chromium-rich types 309 (S30900) and 310 (S31000) and the niobium/tantalum-containing type 347 (S34700) stainless steel suffer extremely high rates of corrosion. Type 304 (S30400) stainless steel is confirmed as having unacceptable rates relative to steel, and the most resistant materials are nickel 200 (N02200) and nickel alloys 400 (N04400) and 600 (N06600).

In AHF liquid, the leaner nickel alloys such as alloys 20 (N08020), 825 (N08825), and the G family are highly resistant to corrosion at temperatures up to  $\sim 125^\circ\text{C}$ , even under flowing conditions, and find significant application, subject to appropriate mitigation of risks relating to preferential weld corrosion and HSC of heavily cold-worked material.<sup>6</sup> The more

**Figure 10** Weight change of nickel exposed to anhydrous hydrogen chloride gas as a function of temperature. Adapted from Ihara, Y.; Ohgame, S.; Sakiyama, K.; Hashimoto, K. *Corros. Sci.* **1982**, 22, 901.

**Figure 11** Corrosion rates for various metals and alloys tested for 4–15 h in anhydrous hydrogen fluoride (AHF) at 600°C. Adapted from Myers, W. R.; Delong, W. B. *Chem. Eng. Prog.* **1948**, 44, 359.

nickel-rich alloys 600 (N06600), C-22 (N06022), and C-276 (N10276) are even more resistant, as illustrated in **Figure 12** that shows corrosion rates for various metals and alloys tested for 6–40 days in AHF at 15–40°C.<sup>6</sup>

The nickel–chromium and nickel–chromium–molybdenum alloys are used at temperatures up to at least ~150°C, but appropriate precautions are also necessary with the nickel-rich alloys to avoid environmental cracking. Thus, the nickel–copper alloys 400 (N04400) and 500 (N05500) have excellent general corrosion resistance but are vulnerable to environmental cracking in the presence of air. Alloy 600 (N06600) has shown a vulnerability to cracking in the presence of chlorine and copper fluoride after cold forming.

**Figure 12** Corrosion rates for various metals and alloys tested for 6–40 days in AHF at 15–40°C. Adapted from Jennings, H. S. *Corrosion by Hydrogen Fluoride and Hydrofluoric Acid*. In *ASM Handbook. Corrosion: Environments and Industries*; ASM International, 2006; pp 690–703, Vol. 13C.

Such risks can be mitigated by appropriate heat treatment procedures.<sup>6</sup>

The basic electrochemistry of the classes of alloys of commercial significance for aqueous hydrohalic acid duties is illustrated by the polarization curves in **Figure 13** for nickel and three nickel alloys in aqueous hydrochloric acid.

Evidently, the corrosion potentials and polarization characteristics of nickel 200 (N02200) and the nickel–copper alloy 400 (N04400) in deaerated 5N (~18%, w/w) hydrochloric acid at room temperature are very similar.<sup>23</sup> Both display very active corrosion potentials and anodic polarization behavior characteristic of active dissolution of the base elements with no tendency to passive film formation:

The polarization curves in **Figure 13** and **Figure 3** confirm the much greater resistance to active, anodic dissolution that nickel displays relative to iron under similar conditions. That is the basis of the generally better performances of nickel-based compared with iron-based alloys in hydrochloric acid. Regarding the specific effects of alloying with copper, the curves in **Figure 13** suggest slightly more polarization of both anodic and cathodic processes in the case of alloy 400 (N04400) than for nickel 200 (N02200), but this depends very much on acid concentration and temperature. Alloy 400 (N04400) is more sensitive to increases in concentration and less sensitive to increases in temperature than nickel 200. In practice, both alloys

**Figure 13** Polarization behavior of (a) alloys B-3 and C-2000 in deaerated 20% (w/w) hydrochloric acid at 25 °C. Adapted from Nacera, S. M.; Crook, P.; Klarstrom, D. L.; Rebak, R. B. *Effect of Ferric Ions on the Corrosion Performance of Nickel Alloys in Hydrochloric Acid Solutions*, Paper 04430, Corrosion 2004: NACE.

have acceptable resistance to corrosion in relatively dilute ( $<10\%$ , w/w) acids at ambient temperatures but at higher concentrations and temperatures, and particularly if oxygen or other oxidizing agents are present, their application is limited.

The more important alloying elements for resistance to aqueous hydrochloric acid are molybdenum and chromium, exemplified by the polarization curves in [Figure 13](#) for the nickel–molybdenum alloy B-3 (N10675) and the nickel–chromium–molybdenum alloy C-2000 (N06200) in deaerated 20% (w/w) hydrochloric acid at 25 °C.<sup>24</sup> Both alloys exhibit relatively active corrosion potentials, albeit more noble than for nickel 200 (N02200) or the nickel–copper alloy 400 (N04400) under similar conditions. Active dissolution is clearly inhibited in the nickel–molybdenum alloy B-3 (N10675) relative to nickel 200 (N02200), arising from the significant contribution of molybdenum to overall dissolution:

The mechanism via which molybdenum inhibits dissolution has been variously attributed to the relatively high Mo–Mo bond energy that blocks active sites<sup>25,26</sup> and the promotion of salt film formation due to the relative insolubility of molybdenum chlorides.<sup>27</sup> It has been suggested that the pseudo-passive behavior,

exemplified by the anodic polarization curve for alloy B-3 (N10675) in [Figure 13](#), may be due to the formation of a molybdenum dioxide ( $\text{MoO}_2$ ) and/or trioxide ( $\text{MoO}_3$ ) film<sup>24</sup> that breaks down under further anodic polarization. Whatever the mechanism, the inhibiting effect of molybdenum on the anodic dissolution of nickel in hydrochloric acid is of significant practical benefit, exemplified by the isocorrosion diagrams in [Figure 14](#) that show the performance of alloy B-2 (N10665) relative to other metals and alloys with exceptional resistance to aqueous hydrochloric acid.<sup>28</sup> However, the absence of the capacity of nickel–molybdenum alloys to passivate, which is apparent in the anodic polarization curve for alloy B-3 (N10675) in [Figure 13](#) signals a sensitivity to the presence of oxidizing agents which limits their practical application, as described later.

In contrast to alloy B-3 (N10675), the anodic polarization curve for the chromium-containing alloy C-2000 (N06200) in [Figure 13](#) shows a pronounced capacity to passivate, which offers the prospect of useful corrosion performance in environments that have sufficient oxidizing capacity to exceed the critical current density for passivation and raise the potential into the passivation range. The active portion of the curve describes active dissolution of the alloy to produce, in addition to  $\text{Ni}^{2+}$  and  $\text{Mo}^{3+}$ , soluble

**Figure 14** Isocorrosion charts ( $0.13 \text{ mm year}^{-1}$ ) for various metals and alloys in hydrochloric acid. Adapted from Hunkeler, F. J. Tantalum and Niobium. In *Process Industries Corrosion*; Moniz, B. J., Pollock, W. J., Eds.; NACE International: Houston, TX, 1986.

chromous ions as follows:

The active dissolution curve is less polarized than alloy B-3 (N10675) due to its lower molybdenum content. At a potential in the 50–100 mV range, the current density drops by more than two orders of magnitude, signaling the formation of a protective passive film. The passive films that form on nickel–chromium and nickel–chromium–molybdenum alloys have been shown to be thin ( $<10 \text{ nm}$ ), and to consist mostly of chromium oxide,  $\text{Cr}_2\text{O}_3$ . An Auger electron spectroscopic (AES) study showed the presence of outer nickel and iron oxides over an inner chromium oxide layer on alloy 600 (N06600), but nickel oxide only in the case of alloy C-4 (N06455).<sup>29</sup> An X-ray photoelectron spectroscopic (XPS) study differentiated inner chromium oxide and outer hydroxide layers.<sup>30</sup> A study using both XPS and time of flight secondary ion mass spectrometry (TOF SIMS) suggested a threshold concentration of chromium in an alloy of  $\sim 20\%$  to promote strong passivity, above which thicker oxides developed with layered structures consisting of inner Cr–Ni and outer Cr–Mo oxides. Molybdenum and tungsten exert little discernible effect on passivation at potentials below  $\sim 200 \text{ mV}$ , when  $\text{Cr}^{3+}$  is the only possible chromium dissolution

product. However, they appear to suppress passive film dissolution at potentials  $> \sim 500 \text{ mV}$ , when transpassive oxidation to  $\text{Cr}^{6+}$  is possible.<sup>31</sup>

The relative performances of nickel–chromium and nickel–chromium–molybdenum alloys in aqueous hydrochloric acid will depend on their compositions, as illustrated in the isocorrosion diagrams in **Figure 15** for a range of alloys relative to the stainless steel 25–6MO (N08926) (note that these are isocorrosion diagrams for a corrosion rate of  $0.5 \text{ mm year}^{-1}$  which is not an acceptable corrosion rate for most practical applications).<sup>32</sup>

Clearly, all of the alloys have significant limitations and none perform as well as the nickel–molybdenum, B family of alloys at concentrations above  $\sim 25\%$  (w/w) pure acid. Alloy 825 (N08825) is the leanest in relation to both nickel and molybdenum contents, and is, therefore, the poorest performer. Alloy 625s (N06625) poor performance relates mainly to its relatively low molybdenum content. The remainder has similar resistances, the marginal differences amongst them reflecting mainly their relatively high, but differing molybdenum and tungsten contents.

There is relatively little published data on the behavior of nickel alloys in aqueous hydrobromic acid, but such data suggest that their relative performances are broadly similar to those in hydrochloric acid. However, hydrobromic acid appears to be less aggressive than hydrochloric acid, despite being a stronger acid, exemplified by the isocorrosion diagrams ( $0.1 \text{ mm year}^{-1}$  for alloy C-22 (N06022) in hydrochloric and hydrobromic acids at concentrations up to  $\sim 5\text{M}$  that are shown in **Figure 16**.<sup>33</sup>

In practice, the performances of nickel alloys in aqueous hydrohalic acids are very often determined by the presence of oxygen or other oxidizing agents that can accelerate markedly the corrosion rates of nickel–molybdenum alloys, or reduce the corrosion rates of chromium-containing alloys by promoting passivity. For example, corrosion rates for alloy B (N10001) tested in aerated and deaerated aqueous hydrochloric acid at  $65\text{--}70^\circ\text{C}$  are shown in **Figure 17**, and the pronounced accelerating effects of aeration, particularly at concentrations below  $\sim 25\%$  (w/w), are evident.<sup>34</sup>

The most pronounced effects are produced by stronger oxidizing agents such as ferric ions, the effects of which on the corrosion of alloys B-3 (N10675) and C-2000 (N06200) in deaerated  $20\%$  (w/w) hydrochloric acid at  $25^\circ\text{C}$  are summarized in **Figure 18**.

**Figure 15** Isocorrosion charts ( $0.5 \text{ mm year}^{-1}$ ) for nickel alloys in hydrochloric acid. Adapted from *High Performance Alloys for Resistance to Aqueous Corrosion*; Publication SMC-026, Special Metals Corporation, 2000.

**Figure 16** Isocorrosion charts ( $0.1 \text{ mm year}^{-1}$ ) for alloy C-22 in hydrochloric and hydrobromic acids at concentrations up to  $\sim 5 \text{ M}$ . Adapted from Meck, N. S.; Pike, L.; Crook, P. Corrosion Performance of a New Age-Hardenable Ni-Cr-Mo Alloy, Paper 08181, Corrosion 2008; NACE International: Houston, TX, 2008.

Evidently, the addition of up to  $\sim 200 \text{ ppm Fe}^{3+}$  increases the corrosion rates of both alloys by increasing their corrosion potentials in the active potential range. Further additions produce progressive increases in the corrosion potential and corrosion rate of alloy B-3 (N10675) which remains active throughout the full potential range, as revealed in the polarization curves for the alloy with and without

**Figure 17** Corrosion rates for alloy B tested in aqueous hydrochloric acid at  $65\text{--}70^\circ\text{C}$ . Adapted from Friend, W. Z. *Corrosion of Nickel and Nickel-Base Alloys*; John Wiley & Sons: London, 1980.

$1000 \text{ ppm Fe}^{3+}$  in **Figure 18**. In the case of alloy C-2000 (N06200), further additions also produce progressive and significant increases in the corrosion potential, but reductions in the corrosion rate by promoting passivation. This is apparent in the polarization curve in **Figure 18** for alloy C-2000 (N06200) in the presence of  $1000 \text{ ppm Fe}^{3+}$  which shows no evidence of an active/passive transition because the material is spontaneously passivated at the outset of the test, as confirmed by its relatively high corrosion potential and the correspondingly low applied current densities required to raise the potential above the corrosion potential.<sup>24</sup>

**Figure 18** Corrosion rates, corrosion potentials, and polarization behaviors of alloys B-3 and C-2000 in deaerated 20% (w/w) hydrochloric acid with various additions of ferric ions at 25 °C. Adapted from Nacera, S. M.; Crook, P.; Klarstrom, D. L.; Rebak, R. B. *Effect of Ferric Ions on the Corrosion Performance of Nickel Alloys in Hydrochloric Acid Solutions*, Paper 04430, Corrosion 2004; NACE International: Houston, TX, 2004.

Nickel and its alloys are among the more corrosion resistant materials in aqueous HF acid, and their relative performances up to the relevant atmospheric boiling point are summarized relative to the stainless steel type 316L (S31603) in the isocorrosion diagrams in [Figure 19](#) (note that these are isocorrosion diagrams for a corrosion rate of  $0.5 \text{ mm year}^{-1}$  which is not an acceptable corrosion rate for most practical applications).<sup>35</sup>

Corrosion rates increase generally with concentration and temperature, and the nickel–copper and nickel–molybdenum alloys outperform significantly the nickel–chromium–molybdenum alloys in the pure acid. Behavior is influenced strongly by the formation and persistence or otherwise of pseudo-passive, fluoride films. However, as with the other acids, the presence of oxygen and other oxidizing agents play a key role and can dominate materials performance, particularly in the cases of nickel–copper and nickel–molybdenum alloys. As a result, the performances of alloys can vary significantly between

liquid and vapor phases as shown in the corrosion rates for various nickel alloys tested in and above 10% (w/w) HF acid at 24 and 76 °C that are charted in [Figure 20](#).<sup>36</sup>

Thus, all the alloys perform relatively well in the liquid phase but nickel 200 (N02200) and alloys 400 (N04400) and 600 (N06600) perform very poorly in the vapor phase at both temperatures. The corrosion rates of alloy C-22 (N06022) also increase in the vapor phase, but not to the same extent as the other alloys that were tested.

These effects are all due to the increased availability of oxygen in the thin, liquid films that condense in the vapor phase. In the case of the chromium-free alloys 200 (N02200) and 400 (N04400) or chromium-deficient alloy 600 (N06600), corrosion product accumulation in the liquid films promotes progressively increased rates of corrosion. Thus, in the case of alloy 400 (N04400), cuprous ions ( $\text{Cu}^+$ ) that are the initial products of dissolution are oxidized by oxygen to the cupric state ( $\text{Cu}^{2+}$ ) in which they induce further

**Figure 19** Isocorrosion charts ( $0.5 \text{ mm year}^{-1}$ ) for nickel alloys in aqueous hydrofluoric acid. Adapted from Crum, J. R.; Smith, G. D.; McNallan, M. J.; Hirnyj, S. *Characterisation of Corrosion Resistant Materials in Low and High Temperature HF Environments*, Paper 382, Corrosion '99; NACE International: Houston, TX, 1999.

**Figure 20** Corrosion rates for various nickel alloys tested in (liquid, L) and above (vapor, V) 10% (w/w) hydrofluoric acid at 24°C and 76°C. Adapted from Pawel, S. J. *Corrosion* **1994**, 50, 963–971.

increases in corrosion potential and corrosion rate. In contrast, the chromium-containing alloy C-22 (N06022) performs better in the vapor phase because passive film formation, albeit relatively non-protective, is possible. Clearly, this is a significant consideration in selecting nickel alloys for aqueous HF acid duties. Other significant factors include:

1. Niobium has an adverse effect on the corrosion resistance of nickel alloys, exemplified by the relatively poor performance of alloy 625 (N06625) that

contains a nominal 3.7% niobium, as shown in [Figure 19](#).

2. Segregation of specific elements, not least niobium, can result in preferential corrosion of welds in nickel alloys.<sup>6</sup>
3. SCC is a significant threat to nickel alloys in aqueous HF acid. Nickel 200 (N02200) and alloys 400 (N04400), 500 (N05500), 600 (N06600), B-2 (N10665), and C-276 (N10276) have all been reported as vulnerable under specific environmental conditions, in particular in vapors over 48% (w/w) acid. The risks of SCC are exacerbated by cold work, and the presence of oxygen and  $\text{Cu}^{2+}$  and can be mitigated by appropriate heat treatment.<sup>6</sup>

The very different behaviors of the nickel–molybdenum B and nickel–chromium–molybdenum C families of alloys have stimulated interest in alloy compositions that might provide both the resistance to anodic dissolution of the B family and the capacity to passivate of the C family. For example, a proprietary alloy Hybrid BC-1 has recently been developed<sup>37</sup> containing 22% molybdenum and 15% chromium that outperforms significantly the other members of the C family of alloys in aqueous hydrochloric and hydrobromic acid solutions, and maintains its performance in the presence of oxygen. For example, corrosion rates for the new alloy and various members of the C family of alloys in tests in hydrochloric acid at concentrations in the range 5–20% (w/w) at  $\sim 80^\circ\text{C}$  are shown in [Figure 21](#). Clearly, the

**Figure 21** Corrosion rates for various nickel–chromium–molybdenum alloys tested in aqueous hydrochloric acid at 79 °C. Adapted from Crook, P.; Meck, N. S.; Koon, N. E. *The Corrosion Characteristics of a Uniquely Versatile Nickel Alloy*, Paper 08190, Corrosion 2008; NACE International: Houston, TX, 2008.

new alloy performs significantly better than any of the other alloys tested, but the prevailing rates of  $\sim 0.5 \text{ mm year}^{-1}$  that apply across much of the concentration range are of limited practical benefit.

## 2.22.5 Other Metals and Alloys

### 2.22.5.1 Copper and Copper Alloys

Copper has limited resistance to anhydrous hydrogen chloride gas, with a suggested upper temperature limit for continuous service below 100 °C. Copper and some of its alloys are, however, much more resistant to AHF gas and liquid, as shown in [Figures 11 and 12](#). Copper has been used at ambient temperatures to handle AHF liquid and vapor and the cupro–nickels (C71000, C71500), in particular, have useful resistance, and have been used for heat exchanger tubing because of their relative resistance to flowing AHF.<sup>6</sup>

Copper might be expected to resist aqueous hydrochloric acid because it is relatively noble and does not normally displace hydrogen from acid solutions. However, its resistance is reduced significantly in the presence of air or other oxidizing agents, not least its own corrosion product,  $\text{Cu}^{2+}$ , which can stimulate corrosion autocatalytically. Silicon bronzes (for example, C65500) have found some use at

**Figure 22** Corrosion rates for copper alloys in static, aqueous hydrofluoric acid under air at 60 °C. Adapted from Materials Selector for Hazardous Chemicals. In *Hydrogen Fluoride and Hydrofluoric Acid*; MTI Publication MS-4, Materials Technology Institute of the Process Industries Inc., 2000; Vol. 4.

concentrations  $< 20\%$  (w/w) at moderate temperatures<sup>5</sup> but, in general, applications for copper and its alloys in aqueous hydrochloric acid are limited.

Some copper alloys have useful resistance to aqueous HF acid but only at relatively low velocities in the absence of oxygen or other oxidizing agents. Corrosion rates for some copper alloys in static, aqueous HF acid under air at 60 °C are shown in [Figure 22](#).<sup>3</sup>

Other tests have shown increased rates of corrosion in vapors over aqueous acids due to the presence of oxygen. Copper, cupronickels (C71000, C71500), and aluminum/aluminum–silicon bronzes have all found some application in aqueous acids, but there have been problems with dealloying and SCC.<sup>6</sup>

### 2.22.5.2 Titanium and Titanium Alloys

Titanium and its alloys are dependent on the formation of protective oxide films consisting mostly of titanium dioxide,  $\text{TiO}_2$ , for their resistances to corrosion. Such films require the presence of oxygen or water to form, and as a general rule anhydrous conditions are best avoided. Titanium and its alloys thus have useful resistance to hydrogen chloride gas containing water but anhydrous gas or condensates from water-containing gas can present significant corrosion risks, depending on the temperature.<sup>2</sup>

One of the conditions for protective film formation in aqueous hydrohalic acids, namely the availability of a

cathodic process to elevate the corrosion potential above the potential for passive oxide formation, is satisfied under most conditions because this potential is below the hydrogen evolution potential. However, the solubility of the passive film increases with concentration and temperature. It has also been shown that the protection afforded by the film depends on the conditions under which it forms, in particular the formation rate.<sup>38</sup> Titanium dioxide is attacked strongly by HF acid to a degree that precludes the application of titanium and its alloys in acidic environments containing HF acid or fluorides. The performance of titanium and its alloys in other hydrohalic acids is dominated by the stability of the titanium dioxide film, and applications are limited to relatively weak acids.

**Figure 23** shows isocorrosion curves ( $0.13 \text{ mm year}^{-1}$ ) for commercially pure titanium (ASTM grade 2, R50400), a titanium–nickel–molybdenum alloy (ASTM grade 12, R53400), and a titanium–palladium alloy (ASTM grade 7, R52400) in naturally aerated hydrochloric acid at concentrations up to 35% (w/w).<sup>39</sup> Evidently, pure titanium is restricted

**Figure 23** Isocorrosion charts ( $0.13 \text{ mm year}^{-1}$ ) for titanium and various titanium alloys in hydrochloric acid and in hydrochloric acid containing various levels of ferric ions. Adapted from *Corrosion Resistance of Titanium*; Timet Metals Corporation, 1997.<sup>39</sup>

to concentrations below  $\sim 5\%$  (w/w) even at ambient temperatures. Alloying with palladium significantly improves the corrosion resistance arising from the well established cathodic modification effects of palladium on promoting and sustaining the passivity of titanium, which are described elsewhere in this book.

There is little published data relating to the performance of titanium and its alloys in hydrobromic acid. Apart from the order of hydrohalic acid strengths, it is known that the breakdown potentials of titanium in aqueous halide-containing solutions are in the order: chlorides  $>$  bromides  $>$  iodides,<sup>40</sup> so hydrobromic acid might be expected to be more aggressive than hydrochloric acid. Notwithstanding that, titanium and its alloys do find commercial application in processes that involve exposure to hydrobromic acid, such as in the manufacture of terephthalic acid from *p*-xylene using metal bromide catalysts.

Oxidizing agents in the acid such as dissolved oxygen, chlorine, nitric and chromic acids, and metal cations in higher oxidation states such as ferric,  $\text{Fe}^{3+}$  or cupric,  $\text{Cu}^{2+}$  ions also promote significant increases in corrosion resistance by promoting and sustaining passivity. For example, the effects of progressive additions of up to 125 ppm ferric ions on the performance of commercially pure titanium, (ASTM grade 2, R50400), in aqueous hydrochloric acid is also shown in **Figure 23**. Evidently, the addition of 125 ppm ferric ions extends the acceptable performance boundary to match the performance of the titanium–palladium alloy, (ASTM grade 7, R52400), at lower temperatures.<sup>39</sup> However, even the temporary absence of oxidizing agents can result in a loss of passivity and the addition of palladium to titanium provides a much more robust mechanism for the mitigation of corrosion risk than additions of oxidizing agents to the acid.

### 2.22.5.3 Zirconium and Zirconium Alloys

Zirconium and its alloys are similar to titanium in their dependence on oxide films, composed mainly of  $\text{ZrO}_2$ , to resist corrosion. They are less resistant to anhydrous hydrogen halide gases than titanium and they find no practical application. Zirconium dioxide is also attacked strongly by HF acid to a degree that also precludes the application of zirconium and its alloys in acidic environments containing HF acid or fluorides.

The performance of zirconium and its alloys in other aqueous hydrohalic acids is superior to titanium because the zirconia film is much less soluble than the corresponding titania film on titanium.

Indeed, zirconium is second only to tantalum in its resistance to aqueous hydrochloric acid, exemplified by the isocorrosion diagram for commercial purity zirconium (Zr702, R60702) in [Figure 14](#). The performances of the commercial alloys containing tin (Zr704, R60704) and niobium (Zr705, R60705) are broadly similar, but they may display inferior resistance toward the performance boundary for commercial purity zirconium (Zr702, R60702) in [Figure 14](#). The main threats to the successful performance of zirconium and its alloys in hydrochloric acid are:

1. Strongly oxidizing conditions can result in the potential exceeding the breakdown potential, resulting in the initiation of localized corrosion. Aeration does not present a significant threat in this respect but stronger oxidizing agents such as cupric and ferric ions in sufficient quantities can stimulate significant pitting attack. Galvanic coupling with nobler materials such as graphite can present a similar threat.
2. Galvanic coupling to more active materials can result in the uptake of cathodically produced hydrogen, resulting in the embrittlement and hydriding of zirconium and its alloys, with a consequential loss of ductility.

These risks and their mitigation are described in more detail in the chapter on zirconium and its alloys in this book.

As with titanium, there is little published data relating to the performance of zirconium and its alloys in hydrobromic acid. However, in contrast to titanium, the breakdown potentials of zirconium in aqueous halide-containing solutions are in the order: iodides > bromides > chlorides<sup>41</sup> and it might thus be expected to be less vulnerable to oxidizing agents than in hydrochloric acid.

#### 2.22.5.4 Tantalum and Tantalum Alloys

Tantalum and its alloys are similar to zirconium and titanium in their dependence on the formation of a protective oxide, specifically tantalum pentoxide ( $\text{Ta}_2\text{O}_5$ ), to resist corrosion. Tantalum is resistant to hydrogen chloride and bromide gases up to at least 150 °C, and even at higher temperatures if the gases contain some water. However, in keeping with the other reactive metals, tantalum's protective oxide is attacked strongly by anhydrous and aqueous HF acid to a degree that precludes its application in acidic environments containing HF acid or fluorides.

Tantalum pentoxide is very stable in aqueous hydrochloric acid, and tantalum (R05200) has exceptional corrosion resistance to the acid, as illustrated in [Figure 14](#). Niobium is similar to tantalum, being protected from corrosion by a film of niobium pentoxide,  $\text{Nb}_2\text{O}_5$ . The film is less protective than tantalum pentoxide, as a result of which niobium is considerably less resistant to corrosion in hydrochloric acid than tantalum or zirconium, as shown in [Figure 14](#). Binary alloys of tantalum and niobium deliver performances intermediate between those of the parent metals. The performance of the commercial 2.5% tungsten alloy (R05252) is broadly similar to tantalum metal.

The main threat to the successful performance of tantalum and its alloys in hydrochloric acid is hydrogen embrittlement due to uptake of cathodic hydrogen from the corrosion of tantalum itself or a more active metal to which tantalum is coupled electrically. Tantalum has a high solubility for hydrogen and forms hydrides. It can absorb hydrogen at ambient temperatures but embrittlement arising from the self corrosion of tantalum and its alloys is usually associated with higher temperatures at which significant corrosion rates are experienced. The rate of embrittlement depends on the corrosion rate but the effects are cumulative, and it has been reported<sup>5</sup> in 25% (w/w) hydrochloric acid at 190 °C in which the corrosion rate is no more than 0.025 mm year<sup>-1</sup>.

Hydrogen embrittlement of tantalum can be prevented by electrical isolation from more active equipment items using insulated flanges or by coupling with a more noble metal with a low hydrogen overvoltage such as platinum, either mechanically, or by resistance or spot welding, or brush plating.<sup>2</sup> An area ratio of ~1000:1 Ta:Pt has been shown to be effective, not only in eliminating embrittlement, but also in reducing the corrosion rates of both tantalum and the noble metal, as shown in [Figure 24](#).<sup>42</sup> The presence of oxidizing agents also prevents hydrogen embrittlement by raising the potential of the tantalum. Thus, embrittlement does not occur in chlorine-saturated hydrochloric acid.<sup>2</sup>

Tantalum is also highly resistant to hydrobromic acid but there is much less data in the public arena than for hydrochloric acid. Like titanium, the breakdown potentials of tantalum in aqueous halide-containing solutions are in the order: chlorides > bromides > iodides,<sup>40</sup> so tantalum might be expected to be more vulnerable to the presence of oxidizing agents in hydrobromic than in hydrochloric acid.

**Figure 24** Corrosion rates for uncoupled and coupled tantalum and platinum in concentrated hydrochloric acid at 15–40 °C. Adapted from Bishop, C. R.; Stern, M. *Hydrogen Embrittlement of Tantalum in Aqueous Media*; 17th Annual NACE Conference; National Association of Corrosion Engineers, 1966.

### 2.22.5.5 Noble Metals

Silver, gold, and platinum are highly resistant to the anhydrous hydrogen halides. In anhydrous hydrogen chloride, upper temperature limits of 230, 870, and 1200 °C have been suggested for silver, gold, and platinum, respectively.<sup>5</sup> Silver has found significant application in equipment for AHF in the absence of oxidizing agents and sulfides.<sup>6</sup>

Silver has good but not unlimited resistance to the aqueous hydrohalic acids below the atmospheric boiling point, depending on the temperature, velocity, and the presence or otherwise of oxidizing agents. Gold and platinum are highly resistant below the atmospheric boiling point, although gold is vulnerable to the presence of very strong oxidants such as ferric ions or nitric acid, and platinum is slightly attacked in 36% (w/w) acid at the boiling point<sup>5,6</sup> and more significantly so at higher temperatures, exemplified by the data in Figure 24.

### 2.22.6 Nonmetallic Materials

Given the limitations of most classes of alloys that might be considered for handling hydrohalic acid, and the high cost of the more resistant materials such as nickel, zirconium, and tantalum alloys, it is inevitable that nonmetallic materials play major roles in hydrohalic acid applications. The application of these materials is covered in more detail in the relevant chapters in this book but the more significant materials are as follows.

#### 2.22.6.1 Thermoplastic and Reinforced Thermosetting Materials

In practice, chemical compatibility is but one factor that determines the suitability or otherwise of a thermoplastic material for a specific application. Other factors such as mechanical and fabrication properties, thermal expansion characteristics, permeation properties, etc. are significant design considerations. In practice, other than for small scale equipment, thermoplastics are used more commonly as linings on stronger substrates rather than in solid form, because of reliability and integrity concerns. Permeation is a particular issue in the case of HF acid at higher concentrations and temperatures, and needs to be managed by, for example, the use of manifolded vent holes through the metal<sup>7</sup> in the case of lined metal systems.

Most thermoplastics of commercial significance find applications in the handling of hydrohalic acids. Readers interested in specific applications should consult materials suppliers and the more detailed sources are referenced,<sup>2–8</sup> but the more significant materials are as follows:

1. Polyethylene (PE), depending upon its molecular weight, and polypropylene (PP) have useful resistance. PE tends to be restricted to temperatures close to ambient, but PP has been used at much higher temperatures as a lining material in the handling, for example, of hydrochloric acid.
2. Polyvinyl chloride (PVC) and chlorinated polyvinyl chloride (CPVC) also find uses at lower temperatures, for example, as linings in glass reinforced plastic tanks for the storage of hydrochloric acid. Unplasticized grades are normally specified because plasticized grades have lower chemical resistance.
3. Fluoroplastics are highly resistant to hydrohalic acids, depending upon their degree of fluorination. The highly fluorinated materials polytetrafluoroethylene (PTFE), fluorinated ethylene propylene (FEP), and perfluoroalkoxy (PFA) are resistant to all concentrations of the acids up to and well-beyond their atmospheric boiling points. The less highly fluorinated materials ethylene chlorotrifluoroethylene (ECTFE), ethylene tetrafluoroethylene (ETFE), and polyvinylidene fluoride (PVDF) are also highly resistant but tend to have lower temperature limits for service than the fully fluorinated grades.

Reinforced polyester, epoxy, phenolic, and furane resins all find application in the handling of hydrohalic

acids. Glass reinforced materials (GRP) based on polyester or vinyl ester resins, possibly lined with PVC (so called dual laminate construction), are widely used for the storage and handling of hydrochloric acid at temperatures up to  $\sim 90^{\circ}\text{C}$ , depending on the acid concentration and the specific resin. Glass is attacked by HF acid but constructions using epoxy vinyl esters and corrosion resistant barriers such as carbon veils can be used for handling weaker acids at lower temperatures.

### 2.22.6.2 Elastomers

Natural rubber is used widely as a lining for carbon steel in the storage, transport, and handling of hydrochloric acid. Softer rubbers tend to be restricted to lower temperatures, but hard rubber can tolerate temperatures as high as  $\sim 90^{\circ}\text{C}$ . Natural rubbers are limited to ambient temperatures in HF acid. Chloro- or bromobutyl rubbers are preferred as linings on carbon steel for the storage and transport of up to 70% (w/w) HF acid, up to maximum service temperatures that depend on concentration.

Other elastomers such as butyl, ethylene propylene diene terpolymer (EPDM), and chlorosulphonated PE (such as Hypalon) find niche applications in hydrohalic acids where, for example, the resistance of natural rubber is limited by factors such as the presence of organic contaminants, higher temperatures, or flexibility requirements. Additives such as silica or magnesia compounds are unsuitable for HF acid service, and have to be substituted by materials such as carbon in special grades.

Fluoro- and perfluoroelastomers provide the best resistance to hot and/or concentrated hydrohalic acids, but their high cost tends to limit their use to smaller components such as gaskets and other sealing components.

### 2.22.6.3 Inorganic Materials

Borosilicate glass is highly resistant to hydrochloric and hydrobromic acids up to temperatures well beyond their atmospheric boiling points, and solid or glass lined equipment finds significant use for handling the acids. However, glass is heavily attacked by HF acid for which it is unsuitable.

Impervious graphite, filled with impregnants such as phenolic resins, PTFE, or carbon, is highly resistant to hydrohalic acids and finds significant use in heat exchange duties for temperatures well-beyond atmospheric boiling. Carbon-carbon composites have excellent resistance to hydrohalic acids and found application for internal components, particularly in

HF acid duties. Carbon bricks with appropriate mortars and fluoroplastic membranes have found applications as linings for steel in high temperature duties. Silicon carbide also has excellent hydrohalic acid resistance and has been used in heat exchange duties.

### 2.23.1 Introduction

Sulfuric acid ( $\text{H}_2\text{SO}_4$ ) is a major feedstock for many chemical processes and is manufactured in greater quantities than any other chemical, most commonly

by the contact process, in which sulfur or sulfur-containing waste is burned to form sulfur dioxide ( $\text{SO}_2$ ), which is converted to sulfur trioxide ( $\text{SO}_3$ ) by contact with a vanadium catalyst and absorbed in acid to increase its strength. The structure of sulfuric acid solutions as a function of concentration is summarized in Figure 1.<sup>1</sup> From the corrosion standpoint, acids are conventionally classified into three concentration ranges:

1. Weak acids with concentrations  $< \sim 25\%$  by weight (w/w). The dominant species are water molecules in which the acid is dissociated into protons ( $\text{H}^+$ ) and bisulfate ( $\text{HSO}_4^-$ ) and sulfate ( $\text{SO}_4^{2-}$ ) anions. Below a concentration of  $\sim 5\%$  (w/w), acid strengths are commonly defined by pH. At the higher end of the pH range, the solutions are effectively acidified waters. Thus, pHs of 2, 3, and 4 are equivalent to concentrations of 490, 49, and 4.9 ppm (w/w) sulfuric acid respectively at  $25^\circ\text{C}$ .
2. Medium-strength acids with concentrations in the range 25–80% (w/w), toward the upper end of which the thermodynamic activity of water decreases to low values while acid molecules are dissociated into protons and bisulfate ( $\text{HSO}_4^-$ ) anions.
3. Concentrated acids, with strengths  $> \sim 80\%$  (w/w), which contain little free water. At the lower end of the concentration range, acid molecules are dissociated into protons and bisulfate ( $\text{HSO}_4^-$ ) anions but undissociated  $\text{H}_2\text{SO}_4$  molecules dominate as

the concentration increases. This includes all of the significant commercial grades of acid, the commonest of which have strengths within the range 93–99% (w/w). Oleums are fuming acids that contain an excess of uncombined  $\text{SO}_3$ , defined in terms of either the free  $\text{SO}_3$  content or the concentration of sulfuric acid equivalent to the contained  $\text{H}_2\text{SO}_4$  plus the acid content that would form if the  $\text{SO}_3$  were reacted with water to form additional acid. Thus, 20% oleum is equivalent to 104.5% (w/w) sulfuric acid.

Sulfuric acid can be either ‘reducing’ or ‘oxidizing’ depending on its concentration. These are rather loose terms, not least because their common usage invariably fails to define the material to which the adjective applies. Conventionally, a reducing acid is one in which cathodic activity is confined to the reduction of protons to evolve hydrogen:

An oxidizing acid is one in which reductions of the acid itself, or its constituent species, occur at potentials more noble than hydrogen evolution and to an extent that can determine the behaviors of materials exposed to the acid. The terms have some validity as descriptors of the hydro-halic acids as inherently reducing and nitric acid as inherently oxidizing, but otherwise they are rather imprecise terms that are potentially misleading. Notwithstanding that, sulfuric acid exhibits inherently reducing or oxidizing properties, depending

**Figure 1** Structure of sulfuric acid solutions. Adapted from Hammer, W. J. *The Structure of Electrolyte Solutions*; J. Wiley, 1959.

on the concentration and temperature. Thus, weak sulfuric acid is inherently reducing but concentrated sulfuric acid is inherently oxidizing, because both bisulfate anions and undissociated acid molecules contain sulfur in the  $S^{6+}$  oxidation state that can be reduced to sulfur dioxide, sulfur, or hydrogen sulfide, in which sulfur is in the  $S^{4+}$ ,  $S^0$ , and  $S^{2-}$  oxidation states, respectively. These reductions can be described stoichiometrically as follows:

Medium-strength acids can be inherently reducing or oxidizing. Dillon<sup>1</sup> has pointed out that 25% (w/w) acid is reduced to sulfur by finely divided nickel at ambient temperatures and by alloy 400 (Ni–30%Cu) at the boiling point, and on that basis, would be classified as oxidizing. However, 25% (w/w) acid corrodes steels and stainless steels rapidly at and above ambient temperatures supported by hydrogen evolution, which classifies it as reducing. As a general rule, hotter, more concentrated acids in the medium concentration range are more likely to exhibit oxidizing properties.

In practice, the extent to which a particular strength of acid is reducing or oxidizing at a particular temperature is also influenced and possibly dominated by the presence or otherwise of specific contaminants, in particular, oxidants, such as dissolved oxygen, nitric acid, and metal cations in a higher oxidation state, such as  $\text{Fe}^{3+}$  or  $\text{Cu}^{2+}$ , that can be beneficial or detrimental to corrosion performance, depending upon the circumstances. However, the presence of reducing agents, such as sulfites and sulfides, is usually detrimental, and halides, notably the ubiquitous chlorides, can have significant adverse effects on the corrosion performances of specific materials, particularly in weak- and medium-strength acids.

The corrosion performances of the various classes of material in sulfuric acid have been reviewed extensively elsewhere<sup>2–7</sup>, and readers whose main interest is to identify ‘what works where’ are referred to these sources and the relevant chapters on specific materials in this book. An exhaustive literature survey of corrosion in sulfuric acid has also been published.<sup>8</sup> In this chapter, the corrosion performances of materials are reviewed with an emphasis on the principles and

mechanisms that underpin their corrosion performances in sulfuric acid.

## 2.23.2 Steels and Cast Irons

Steels and gray or ductile cast irons are active and corroded rapidly by weak- and medium-strength acids. However, they have useful corrosion resistance in concentrated acids under static or low flow conditions as illustrated by the corrosion rate (CR) data in **Figure 2** relating to the performances of steel and gray or ductile cast irons in acid concentrations above 80% (w/w) at a temperature of 27 °C under stagnant conditions.<sup>2</sup>

The corrosion resistance arises from the spontaneous formation of protective films on steel and cast iron surfaces in concentrated acids. The potential to form such films is illustrated in **Figure 3** that shows anodic polarization curves for gray cast iron in stagnant 20% (w/w) sulfuric acid at 30 and 60 °C.<sup>9</sup> Gray cast iron corrodes rapidly at its natural corrosion potential in 20% (w/w) sulfuric acid at both temperatures, but the CR is reduced significantly in stages by anodic polarization, initially as the potential increases through a less protective sulfation region into a much more protective passivation region. The sulfation process involves the formation of a supersaturated

**Figure 2** Corrosion rates of steel and cast iron in concentrated sulfuric acid under stagnant conditions. **Figure 3** Anodic polarization curves for grey cast iron in 20% (w/w) sulfuric acid. Adapted from Breakell, J. E. *The Corrosive Wear of Cast Irons in Marine Diesel Engine Cylinder Environments*; Ph. D. Thesis, University of Manchester, October, 1980.<sup>9</sup>

solution of ferrous sulfate, from which a crystalline film nucleates and grows. The degree of hydration of this film is thought to vary with acid strength as the concentration of water reduces from the heptahydrate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ) in dilute acids through the monohydrate ( $\text{FeSO}_4 \cdot \text{H}_2\text{O}$ ) in the 60–70% (w/w) concentration range to  $2\text{FeSO}_4 \cdot \text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$  in the 75–85% (w/w) concentration range and  $\text{FeSO}_4 \cdot 3\text{H}_2\text{SO}_4$  in 96% (w/w) acid.<sup>10</sup> This is the archetypal process underpinning the more general salt-film formation on metals, which may (as in this case) limit the CR by providing a diffusion barrier to reactive species.

As electrochemical potentials increase further into the passivation range, the ferrous salts are thought to oxidize progressively to ferric salts such as  $\text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{O}$  and  $\text{Fe}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{SO}_4$  in concentrated solutions and ferric oxide centers nucleate and grow in the mixed ferrous–ferric salt film.<sup>10</sup> The passive film has been shown by X-ray photoelectron spectroscopy (XPS) to consist of a hydrated oxy-hydroxide layer across all acid concentrations. In weak acids, the film is thin as a result of the reaction of iron with water. As the acid concentration increases, progressively thicker, less hydrated films with higher contents of oxide phase are formed containing sulfates ( $\text{S}^{6+}$ ) at their surfaces but sulfur species in oxidation state  $\text{S}^{2-}$

in their bulks, confirming that acid reduction plays an integral role in the passivation process.<sup>11</sup>

In practice, the natural, open circuit potentials of steels and gray or ductile cast irons in concentrated acids are confined to the sulfation potential range, and their corrosion behaviors are determined essentially by the dissolution rates of the iron sulfate films on their surfaces. These are determined in practice by mass transport control of the diffusion of dissolved iron sulfate away from the surface in the prevailing conditions of acid concentration, temperature, velocity, and the presence or otherwise of dissolved iron in the acid. Convective mass transfer rates have been modeled for turbulent flow in a variety of geometries and for the case of a steel pipe protected by a layer of iron sulfate that remains constant with time (ie any loss of the layer is compensated for by further corrosion of the steel), the following expression for calculating the corrosion rate (CR) can be derived.<sup>12</sup>

$$\text{CR} = 1.42 \times 10^{-4} T^{-0.654} u^{0.913} \rho^{1.567} \mu^{-1.221} d^{-0.087} (C_{\text{surface}} - C_{\text{bulk}})$$

Since  $T$ ,  $u$ ,  $\rho$ ,  $\mu$  and  $d$ , and  $C_{\text{surface}}$  are all known for the concentration of acid at the temperature in question, the CR can be calculated if  $C_{\text{bulk}}$  is known.  $C_{\text{bulk}}$  could be assumed to be zero, in which case a maximum CR would be calculated. However, in practice commercial acid always contains some ferrous sulfate, having been produced and handled in carbon steel equipment, and therefore,  $C_{\text{bulk}}$  can either be measured, or assumed to be typically  $\sim 100$  ppm ( $\sim 0.01\%$  w/w), in which case a rate correspondingly lower than the zero case is calculated. In practice, an excellent correlation between calculated and observed CRs in pipes is obtained, confirming that the corrosion of steel is dominated by mass transport control of the diffusion of dissolved iron sulfate away from the corroding surface.<sup>12</sup>

The CRs in Figure 2 underpin the widespread use of carbon steels and gray/ductile irons for the storage and piping of commercial grades of sulfuric acids with concentrations in the range 93–99% (w/w) at near-ambient temperatures. However, the protective sulfate films are very vulnerable to disturbance. Velocities in steel piping systems have to be restricted<sup>2</sup> to  $\sim 0.6 \text{ m s}^{-1}$  or less. In steel storage tanks, if roof inlet nozzles are too close to the shell wall, during filling, turbulence adjacent to the wall can promote rapid dissolution of the protective iron sulfate film, resulting in accelerated local corrosion. Bubbles of cathodically produced hydrogen ascend vertically, disrupting the

protective film, causing vertical corrosion grooves at CRs up to several millimeters per year, as shown in **Figure 4**. Gray and ductile cast irons perform in a manner similar to that of steels in concentrated acids, as confirmed in **Figure 2**. However, gray irons have slightly better temperature and velocity tolerances that have been attributed to an ennoblement of corrosion potential by the graphite flake network, resulting in a sulfate film that is more resistant to dissolution and disturbance.

High-silicon cast irons, containing typically 14–16% Si (e.g., F47003), are very resistant to all concentrations of sulfuric acid up to 100% (w/w) at temperatures up to their boiling points at atmospheric pressure. Their corrosion resistance is due to the formation of robust, siliceous films that have considerable resistance to erosion and abrasion. Unfortunately, their exceptional resistance finds relatively limited application because of their poor ductility that renders them difficult to fabricate and requires them to be protected from thermal and/or mechanical shock.

Electrochemical anodic protection can be used to reinforce passivity steel in concentrated acids, as described in the separate chapter on anodic protection in this book. CRs can be reduced by up to 80%, which can be beneficial, for example, in controlling the iron content of acids in steel storages. However, anodic protection of gray cast irons can result in cracking by a

mechanism similar to that described in oleum in the following paragraph.

In oleum, steel experiences relatively high rates of corrosion in the 100–101% (w/w) acid concentration range at near-ambient temperatures that drop to acceptable levels as the concentration increases, arguably beyond  $\sim 102.5\%$  and certainly beyond 105% acid (w/w). Ductile irons behave similarly, but gray flake irons cannot be used in oleum, because they are vulnerable to cracking, triggered, it is thought, by the oxidation of graphite flake surfaces by free  $\text{SO}_3$  resulting in penetrating volumetric expansion and associated strains. High-silicon cast irons are also rapidly attacked by  $\text{SO}_3$  in oleum.

## 2.23.3 Stainless Steels

### 2.23.3.1 Mechanisms of Protection

The compositions of some of the more important stainless steels for sulfuric acid applications are summarized in **Table 1**. The behavior of stainless steels in sulfuric acid is determined by the presence or otherwise of passive surface films that are composed mostly of chromium oxide formed from the chromium in the alloy. The compositions and structures of the films can be modified by other alloying elements, in particular, molybdenum and silicon, resulting in changes in the

**Figure 4** Hydrogen grooving of the wall of a concentrated sulfuric acid storage tank. Adapted from *Materials Selector for Hazardous Chemicals Vol. 1: Concentrated Sulphuric Acid and Oleum (2nd ed.)*; MTI Publication MS-1, Materials Technology Institute of the Process Industries Inc., 2005.

behaviors of the films under specific conditions of concentration and temperature.

The potential benefits that alloying with chromium provides are illustrated by the polarization curves in [Figure 5](#) for iron, chromium, and type 430 (S43000) ferritic stainless steel that were obtained in agitated, 93.5% (w/w) sulfuric acid at 60 °C.<sup>13</sup> All the three anodic curves show an initial limiting current plateau preceding an active–passive transition as the potential is increased. The limiting current in all the cases results from the convective diffusion of  $\text{Fe}^{2+}$  and  $\text{Cr}^{2+}$  into the bulk liquid from a saturated sulfate salt layer. However, the plateau persists over a much wider potential range for iron than for chromium and the type 430 stainless steel, both of which show well developed passivity at much lower potentials and at current densities several orders of magnitude lower than for iron.

XPS studies of the passive layer on chromium in sulfuric acid<sup>14,15</sup> have shown it to consist of chromium oxy-hydroxides across the full range of acid concentrations. As in the case of iron, in weak- and medium-strength acids, passivation results from the reaction of chromium with water molecules from the acid:

However, in concentrated acids, bisulfate ( $\text{HSO}_4^-$ ) anions and undissociated acid molecules provide the oxygen:

**Figure 5** Potentiodynamic anodic polarization behavior of iron, chromium and S43000 (Fe~18%Cr) ferritic stainless steel in stirred 93.5% (w/w) sulfuric acid at 60 °C. Adapted from Kish, J. R.; Ives, M. B.; Rodda, J. R. *Corros. Sci.* **2003**, *45*, 1571–1594.

The films formed in concentrated acids contain sulfur species in lower oxidation states ( $\text{S}^{2-}$ ) than in the acid ( $\text{S}^{6+}$ ), confirming that acid reduction plays an integral role in the passivation process.

The passive films that form on stainless steels in sulfuric acid are very similar in structure and thickness to the chromium oxy-hydroxide films that form on chromium metal.<sup>16,17</sup> However, the formation or otherwise of the films depends on the presence and concentration of elements other than chromium in the base material. Thus, it is clear from the polarization curve shown in **Figure 5** for type 430 stainless steel that the steel does not passivate spontaneously under the conditions tested, because the reductions of bisulfate anions and undissociated acid molecules cannot occur at sufficient rates to exceed the limiting current density for passivation. However, under the same conditions, type 304 (S30400) austenitic stainless steel exhibits spontaneous, periodic oscillations of corrosion potential between the active and passive states, as shown in **Figures 6(a) and 6(b)** on different time bases.<sup>18</sup> These oscillations have been studied by several workers<sup>19–22</sup>, and it is generally agreed that they result from the formation of an intermediate corrosion product in the active state that promotes passivation, which is subsequently redissolved resulting in reactivation. Since only nickel-containing steels exhibit oscillations, the intermediate corrosion product is believed to be a nickel salt, probably nickel sulfide, and a sequence of reactions that give rise to the oscillations has been proposed in four stages, as in **Figure 6(b)**:

1. The potential decrease from zero time to point one results from the dissolution of the nickel sulfide film and subsequently, the passive film.
2. The rapid potential drop between points one and two is associated with the active dissolution of the alloying elements as  $\text{Fe}^{2+}$ ,  $\text{Ni}^{2+}$ , and  $\text{Cr}^{3+}$  supported by acid reduction to sulfide,  $\text{S}^{2-}$ .
3. The gradual rise in potential between points two and three is associated with the nucleation and growth of nickel sulfide on the active surface.
4. Nickel sulfide increases the exchange current density for acid reduction to levels at which passivation occurs spontaneously, signaled by a rapid rise in potential between points three and four.

This sequence is the basis for the significant improvements in corrosion resistance of stainless steels in sulfuric acid that result from alloying with nickel at modest levels, although as the level in the alloy increases, nickel's effect in retarding active dissolution of the alloy also becomes significant. Three other alloying elements bring additional improvements:

**Figure 6** Potential of type 304L austenitic stainless steel in 93.5% (w/w) sulfuric acid at 60 °C as a function of time (a) typical active passive oscillations (b) dominant reactions in a single oscillation. Adapted from Li, Y.; Ives, M. B.; Coley, K. S. *Corros. Sci.* **2006**, 48, 1560–1570.

1. Copper promotes the formation of passive films, partly by retarding active dissolution and reducing the critical current density required to form a film, but mostly by depolarizing cathodic processes, including hydrogen evolution, in the form of copper films that redeposit rapidly on active surfaces.<sup>23</sup> The beneficial effect is similar to that delivered by nickel sulfide films, and increases up to a level of 2–3% copper, as illustrated in **Figure 7**.
2. Molybdenum also promotes the formation of passive films by depolarizing cathodic processes, in particular hydrogen evolution. It also retards active dissolution in sulfuric acid by the formation of a molybdenum-rich, stable oxide film in the active region that acts as a diffusion barrier to metal dissolution, thereby reducing the critical current density and lowering the potential required to form a passive film.<sup>24</sup> Molybdenum also modifies the composition and structure of the passive film, being incorporated in the  $\text{Mo}^{6+}$  oxidation state as

**Figure 7** Influence of copper, molybdenum, and chromium contents on corrosion rates of stainless steels and nickel alloys in stagnant 95% sulfuric acid solutions at 100–150 °C. Adapted from Coppolechia, V. D.; Renner, M. H. W.; Rockel, M. B. *Corrosion Resistance of Stainless Steels and Nickel Alloys in Concentrated Sulphuric Acid*; Paper 189, Corrosion '86, NACE International, 1986.

either  $\text{MoO}_3$  or  $\text{MoO}_4^{2-}$ , particularly in the outer regions.<sup>24,25</sup> However, molybdenum increases the vulnerability of the alloy and film to transpassive dissolution,<sup>25</sup> and as a result, molybdenum-containing alloys become vulnerable to corrosion in very concentrated acids and oleum, particularly as temperatures increase, and at levels above ~5% molybdenum, as illustrated in Figure 7.

3. Silicon additions, typically in the range 5–6% (w/w), modify the composition and structure of the passive film, producing silicon-rich films that confer high resistance to corrosion and erosion corrosion in hot acids with concentrations in the 93–99% (w/w) range. However, corrosion resistance drops steeply on either side of this range, and as in the case of high-silicon cast irons, the silicon-rich films are attacked by  $\text{SO}_3$  in oleums, rendering the materials unsuitable for service.

The ease and sustainability of passivation of stainless steels is also a function of the chromium content

itself, as illustrated in Figure 7. This has an influence on the range of sulfuric acid conditions that specific grades of stainless steel can withstand. Most of the widely used materials, such as alloys 304L (S30403), 316L (S31603), 904L (N08904), and 20 (N08020) contain ~20% chromium but are limited by concentration and/or temperature to varying degrees, depending on their contents of other alloying elements. Increased tolerance of temperature and/or concentration is provided by alloys, such as 31 (N08031) and 33 (R20033), that contain ~27% and ~31% chromium, respectively.

Oxidizing agents and aggressive anions exert strong influences on the corrosion of stainless steels in sulfuric acid. Dissolved oxygen has a pronounced effect on the presence or otherwise of passivity, particularly in relatively weak acids, as confirmed in Figure 8, which demonstrates that rates of corrosion for types 304 (S30400), 316 (S31600), 317 (S31700), and 310 (S31000) stainless steels are all higher at

**Figure 8** Effects of aeration on corrosion rates of stainless steels in sulfuric acid solutions at 70°C. Adapted from Phelps, E. H., Vreeland, D. C. *Corrosion* **1957**, 13, 619–624.

concentrations below 30–40% acid at 70 °C when oxygen is absent.<sup>26</sup> Figure 9(a) shows the beneficial effects of additions of Fe<sup>3+</sup> and Cu<sup>2+</sup> as sulfates on the corrosion of type 316L (S31603) stainless steel in 75% and 85% acids at 100 °C.<sup>27</sup> Figure 9(b) confirms the dramatic effect of sufficient (2%) nitric acid that effectively stifles the corrosion of type 316L (S31603) stainless steel in 30% sulfuric acid at 90 °C, but also illustrates that insufficient oxidizing agent, in this case nitric acid (1%), can accelerate, rather than inhibit, corrosion.<sup>28</sup> Other oxidizing agents have been shown to have similar effects, including Cr<sup>6+</sup> added as chromic oxide or chromates and Sn<sup>2+</sup> added as sulfate, which is effective by being reduced to the metallic state.<sup>7</sup> Figure 9(c) shows the significant accelerating effects of 5% sodium chloride additions on the CRs of alloys 316L (S31603), 20 (N08020) and 825 (N08825) in 10% acid at 66 °C, and in practice, much lower levels of chloride can exert significant accelerating effects on corrosion.<sup>7</sup>

The passive films that form on stainless steels are in general much less vulnerable to acid velocity than the sulfate films that form on steels. Thus, maximum velocities up to  $\sim 3.3 \text{ m s}^{-1}$  are recommended for stainless piping systems for commercial grades of sulfuric acids with concentrations in the range 93–99% (w/w) at near-ambient temperatures compared with  $\sim 0.6 \text{ m s}^{-1}$  for steels.<sup>2</sup> Brubaker<sup>4</sup> has pointed out that the sensitivity of CRs of passive stainless steels to velocity depends on how close they are operating to the transitions to

activity or transpassivity, with ‘solidly’ passive stainless steels tolerating relatively high velocities. A good example of this is shown in Figure 10 that shows CRs for different stainless steels in 98.7% (w/w) sulfuric acid at 100 °C as a function of velocity. Clearly, the CRs of alloys 316 (S31600) and 825 (N08825) are very dependent on velocity, whereas the CR of the proprietary alloy 1815LCSi, an austenitic stainless steel containing 4% silicon, is independent of velocity, reflecting the tenacious nature of the passive film formed on high Si-containing stainless steels under these conditions.

Some of the main factors that influence the formation and stability of passive films on stainless steels are summarized schematically in Figure 11. The anodic polarization curves show the familiar active dissolution, passive, and transpassive regions. As the temperature and/or the concentration of aggressive anions, such as chloride increase, the capacity of materials to passivate is squeezed by extended active dissolution and less protective passive regions. Under nonoxidizing conditions, the prevailing cathodic process, hydrogen evolution, anchors the corrosion potential in the active dissolution region of the anodic polarization curve of the material. Under oxidizing conditions, cathodic processes arising from reduction of the acid itself or from the presence of oxidizing agents, such as dissolved oxygen, nitric acid, or metal cations in higher oxidation states, such as Fe<sup>3+</sup> or Cu<sup>2+</sup>, are able to promote passivity.

**Figure 9** Effects of contaminants on the corrosion of 316L stainless steel and other alloys in sulfuric acid (a)  $\text{Cu}^{2+}$  and  $\text{Fe}^{3+}$  additions at 100 °C, adapted from Berglund, G.; Martenson, C. *Application of a High Alloyed Stainless Steel in Sulphuric Acid Environments*; Paper 21, Corrosion '87, NACE International, 1986 (b)  $\text{HNO}_3$  additions at 93 °C, adapted from Kiefer, G. C.; Renshaw, W. G. *Corrosion* **1950**, 6, 235–244 (c)  $\text{Cl}^-$  additions at 66 °C. Adapted from *The Corrosion Resistance of Nickel-Containing Alloys in Sulphuric Acid and Related Compounds*; Corrosion Engineering Bulletin 1, The International Nickel Company, 1983.

Under strongly oxidizing conditions, the cathodic polarization curve intersects the anodic polarization curves at relatively high potentials well into the passive region, and stable passivity is promoted that may well survive the moderate increases in temperature and/or the concentrations of aggressive anions, such as chloride. However, further increases may move the corrosion potential into the transpassive region in the case of temperature, or above a film breakdown potential in the case of aggressive ions, such as chloride, resulting in accelerated corrosion.

Moderately oxidizing conditions may be sufficient to promote passivity at low temperatures and/or concentrations of aggressive anions, such as chloride. However, moderate increases in either can result in multiple intersections of the cathodic and anodic polarization curves, which are indicative of unstable passivity.

Under such borderline conditions, the corrosion potential may oscillate between the passive and active regions, and the CR will lie between the rates that are characteristic of passive and active behavior, depending on the period and frequency of the oscillations.

### 2.23.3.2 Performances of Stainless Steels

The performances of some of the more important stainless steels for sulfuric acid applications are summarized in **Figures 12–14**. The basic austenitic grades, such as 304L (S30403) and 316L (S31603), provide useful resistance to relatively weak, and in particular, strong acids where they find frequent use for storage and transport equipment at concentrations  $>\sim 93\%$  (w/w). The molybdenum-containing 316L (S31603) grade expands the region of stable

**Figure 10** Corrosion rates of different stainless steels in 98.7% (w/w) sulfuric acid at 100 °C as a function of velocity. Adapted from Coppolechia, V. D., Renner, M. H. W., Rockel, M. B. *Corrosion Resistance of Stainless Steels and Nickel Alloys in Concentrated Sulphuric Acid*; Paper 189, Corrosion '86, NACE International, 1986.

**Figure 11** Schematic polarization characteristics of stainless steels in sulfuric acid as a function of temperature ( $T$ ), chloride content ( $\text{Cl}^-$ ) and the inherent oxidizing potential of the acid, and/or the presence of oxidizing contaminants, such as dissolved oxygen, nitric acid or metal cations in higher oxidation states, such as  $\text{Fe}^{3+}$  or  $\text{Cu}^{2+}$ .

passivity relative to type 304L (S30403) and is a candidate, for example, for service in the 90–93% (w/w) concentration range at ambient temperatures, where 304L (S30403) is at greater risk of unstable passivity. In concentrated acids, the upper temperature limit for stable passivity increases with concentration from  $\sim 40^\circ\text{C}$  at 93% to above  $100^\circ\text{C}$  above 99% (w/w), in line with the much greater oxidizing potential of the more concentrated acid. Anodic protection, which is the subject of a separate chapter in this book, can

**Figure 12** Isocorrosion charts ( $0.1 \text{ mm year}^{-1}$ ) for carbon steel and duplex stainless steels in naturally aerated sulfuric acid. Adapted from *Corrosion Handbook, Stainless Steels*; AB Sandvik Steel, 1994.

be of significant benefit in reducing CRs in concentrated acids, as illustrated for type 316 (S31600) stainless steel in Figure 15, and is used routinely for the protection of concentrated acid coolers in sulfuric acid plants.

In weak acids, the molybdenum-containing 316L (S31603) grade shows significantly expanded resistance relative to type 304L (S30403) that has a limited resistance to solutions other than very dilute solutions at temperatures close to ambient, and both grades are vulnerable to loss of passivity in the absence of oxygen. The duplex grades, 2205 (S32205) and 2507 (S32750) grades offer significantly enhanced resistance to weaker acids than the basic austenitic grades, in line with their higher contents of chromium, molybdenum, and copper. However, none of the basic austenitic or duplex grades contains sufficient nickel to provide serviceable corrosion performances in medium-strength acids.

Stainless steel grades that offer useful corrosion resistance to medium strength as well as weak and concentrated acids, contain a minimum of  $\sim 18\%$  nickel, supplemented by significant molybdenum and/or copper contents. The grades that are leaner in nickel, relying more on molybdenum and copper to promote passivation, such as alloys 254SMO (S31254), 25–6MO (N08926), and 27–7MO (S31277), perform particularly well in weaker acids but have lower temperature limits for stable passivity as the concentration rises and relatively poor performances in concentrated acids. The stainless steel grades that offer the most stable passivity across the whole concentration range are alloys 20 (N08020) and 31 (N08031), which contain a minimum of  $\sim 30\%$  nickel

**Figure 13** Isocorrosion charts ( $0.1 \text{ mm year}^{-1}$ ) for austenitic stainless steels in naturally aerated sulfuric acid. Adapted from *Corrosion Handbook, Stainless Steels*; AB Sandvik Steel, 1994.

**Figure 14** Isocorrosion chart ( $0.1 \text{ mm year}^{-1}$ ) for austenitic alloy 31 in lightly aerated sulfuric acid. Adapted from *Material Data Sheet No 4031*, Thyssenkrupp VDM, 2002.

supplemented by molybdenum and copper additions, exemplified by the temperature limits for stable passivity of alloy 31 (N08031) shown in [Figure 14](#).

Acid strengths above 98% (w/w) and oleum are very oxidizing, and the CRs of most stainless steels are correspondingly lower. However, alloys with particularly high molybdenum contents are vulnerable to transpassive corrosion and can underperform the more basic grades of stainless steel, as illustrated in the ranking of various materials in tests under static conditions in 99% (w/w) acid at 100–120 °C shown in [Figure 16](#). Evidently, the most resistant material was type 304L (S30403) stainless steel that outperformed

**Figure 15** Effects of anodic protection on corrosion rates of type 316 stainless steel in 93–98% sulfuric acid at 70 and 100 °C. Adapted from Walker, R. *Anodic protection*. not only the molybdenum-containing alloys 904L (N08904), 20 (N08020), C-276 (N10276), and B-2 (N10665), but also the silicon-containing material S30601. Notwithstanding that, high-silicon stainless steels, such as S30601, have found significant applications in equipment handling concentrated acids at elevated temperatures, as long as there is no risk of oleum formation, to which their resistance is poor. Brubaker<sup>4</sup> has drawn attention to the care that is required in selecting stainless steels for acid concentrations above 98% (w/w) where variations in velocity, oxidant

content and transient acid dilution can adversely affect performance. For oleum duties in particular, stainless steels with high chromium and low molybdenum contents are least vulnerable to such risks. Thus, alloy 33 (R20033) provides very high resistance to hot, concentrated, oxidizing acids, as illustrated in Figure 17, and this extends into the oleum concentration range.

## 2.23.4 Nickel Alloys

### 2.23.4.1 Mechanisms of Protection

The CR of nickel in aerated sulfuric acid as a function of concentration at room temperature is shown in Figure 18.<sup>29</sup> Evidently, CRs peak at  $\sim 1.5 \text{ mm year}^{-1}$  in  $\sim 80\%$  (w/w) acid in the concentration range 0–96% (w/w) acid, which, although unacceptable from the engineering standpoint, is indicative of the

much slower rates of active dissolution of nickel in weak and medium-strength acids compared with iron. Nickel can be used in deaerated sulfuric acid solutions at low temperatures, but in practice, its significant applications in sulfuric acid are alloy form, and the compositions of some of the more important alloys for sulfuric acid service are summarized in Table 1.

The mechanisms of protection of nickel alloys in sulfuric acid are illustrated by the anodic polarization curves for nickel and binary alloys of nickel with copper, molybdenum and chromium in deaerated sulfuric acid in Figure 19.<sup>30–33</sup> The active region for pure nickel is generally much smaller and the passivation potential lower than for iron, but the current density in the passive range remains relatively high, indicative of relatively unprotective passivity. XPS studies of the passive film indicate a duplex structure with an inner NiO and outer  $\text{Ni}(\text{OH})_2$  layers, the solubility of the latter increasing as the pH drops in weak acids.<sup>34</sup> At higher potentials, transpassive dissolution of nickel occurs, particularly at grain boundaries. The effects of alloying elements are as follows:

1. Copper additions move the corrosion and the active/passive transition potentials to more noble values and increase the current densities required to form and sustain passivity, so that in the case of the curve for alloy 400 (N04400), the commercial  $\sim 30\%$  copper alloy, shown in Figure 19(a), the remaining passivity is even less protective than the relatively unprotective films that are characteristic of pure nickel.<sup>31</sup> These curves not only suggest the significant benefits of alloying with copper at potentials in the active region, but also that in the passive region, alloying with copper alone is deleterious to corrosion resistance.

**Figure 16** Corrosion rates for various materials under static conditions in 99% (w/w) acid at 100–120°C. Adapted from Brubaker, S. K., H. Corrosion by Sulfuric Acid. In *ASM Handbook Vol. 13C Corrosion: Environments and Industries*; ASM International, 2006; pp 659–667.

**Figure 18** Corrosion rate of nickel in aerated sulfuric acid at room temperature. Adapted from Fink, C. G.; DeCroly, C. M. *Trans. Am. Electrochem. Soc.* **1929**, 56, 239.

**Figure 19** Anodic polarization curves in deaerated sulfuric acid at 25 °C for nickel and (a) nickel–copper. Adapted from TrabANELLI, G.; Zucchi, F.; Felloni, L. *Corros. Sci.* **1965**, 5, 211. (b) nickel–molybdenum. Adapted from Greene, N. D. *The Passivity of Nickel and Nickel-Base Alloys*; Proceedings of the 1st International Congress on Metallic Corrosion; Butterworth: London, 1962. (c) Nickel–chromium alloys, adapted from Myers, J. R.; Beck, F. H.; Fontana, M. G. *Corrosion* **1965**, 21, 277.

2. Molybdenum additions have effects similar to those of copper additions. The polarization curve for pure molybdenum shown in [Figure 19\(b\)](#), shows no evidence of passive behavior in ~5% (w/w) acid. Alloys with molybdenum additions of up to ~20% (w/w) continue to display passive characteristics but with progressively increasing passive current densities with respect to pure nickel.<sup>32</sup> However, at the 27% (w/w) level that is representative of the commercial B family of alloys, there is no evidence of passivation in the polarization curve shown in [Figure 19\(b\)](#) and the current density increases progressively with potential in a manner similar to that of pure molybdenum. As with copper, the main benefit of molybdenum alloying is in the active region, and in the passive

region, molybdenum is also deleterious to corrosion resistance.

3. Chromium additions confer very pronounced benefits in both active and passive regions of the polarization curve, as shown in [Figure 19\(c\)](#). In practice, levels of chromium of ~9% or more produce significant reductions in the current density in the active region, the potential at which passivation occurs, and the passive current density.<sup>33</sup> At the 23% and 33% (w/w) levels depicted in [Figure 19\(c\)](#), chromium reduces the potential required to form passivity by ~400 mV and the current densities required to form and sustain passivity by up to two orders of magnitude relative to pure nickel.
4. Silicon additions in the range 5–6% (w/w) modify the composition and structure of the passive

film on nickel–chromium alloys by a similar mechanism as in the case of stainless steels, producing silicon-rich films that confer high resistance to corrosion and erosion corrosion in hot acids with concentrations in the 93–99% (w/w) range.

Oxidizing agents and aggressive anions exert influences on the corrosion of nickel alloys that are similar to those observed with stainless steels in sulfuric acid. Thus, the effects of dissolved oxygen and oxidizing agents on nickel–chromium alloys are broadly beneficial in that they help to promote and sustain the formation of protective passive films. However, dissolved oxygen has a significant accelerating effect on the corrosion of nickel metal and nickel–copper and nickel–molybdenum alloys that do not passivate in

the acid. For example, CRs for alloy 400 (N04400) across the concentration range in gently moving acid at 30 °C and alloy B at various acid concentrations and temperatures<sup>7</sup> are shown in **Figure 20(a) and (b)**. The accelerating effects of air in weak and medium-strength acids and the dramatic accelerations in CR in strongly oxidizing, concentrated/hot acids are evident in both cases. Other oxidizing agents, such as metal cations in higher oxidation states, in particular  $\text{Fe}^{3+}$  or  $\text{Cu}^{2+}$ , chromates, nitrates/nitrites, and peroxides exert similar effects, depending on the alloy. Thus, the CR of alloy B-2 (N10665) in boiling 30% (w/w) acid is increased dramatically by  $\text{Fe}^{3+}$  additions at levels in the range of 10s–100s ppm, whereas the CR of alloy C-276 (N10276) is, if anything, lowered under similar conditions as shown in **Figure 21(a) and 21(b)**.<sup>7</sup>

**Figure 20** Effects of aeration on corrosion rates in sulfuric acid of (a) alloy 400 and (b) alloy B. Adapted from *The Corrosion Resistance of Nickel-Containing Alloys in Sulphuric Acid and Related Compounds*; Corrosion Engineering Bulletin 1, The International Nickel Company, 1983.

**Figure 21** Effects of additions of  $\text{Fe}^{3+}$  on the corrosion rate of alloys B-2 and C-276 in boiling 30% (w/w) sulfuric acid. Adapted from *The Corrosion Resistance of Nickel-Containing Alloys in Sulphuric Acid and Related Compounds*; Corrosion Engineering Bulletin 1, The International Nickel Company, 1983.

Chloride contaminants have a general accelerating effect on the CRs but the magnitude of the effect varies, depending on the alloy, as illustrated in **Figure 22** that shows CRs for alloys B-3 (N10675) and C-2000 (N06200) in boiling weak and medium-strength acids in the presence and absence of 200 ppm chloride.<sup>35</sup> Although the presence of chloride increases the CRs of both alloys at all concentrations, the effects are significantly greater for alloy C-2000 (N06200), which depends on passivity for its corrosion resistance. In contrast, for alloy B-3 (N10675) depends on its intrinsic resistance to anodic dissolution in the nonoxidizing environment that is only marginally affected by the presence of a relatively small amount of chloride.

The sensitivity of CRs to acid velocity also varies with the alloy. The CRs of nickel–copper and nickel–molybdenum alloys that do not form passive films are sensitive to the relatively low velocities that determine the rates of mass transfer of oxidants and soluble corrosion products to/from the alloy surface, as illustrated for alloy 400 (N04400) in 5% (w/w) acid in **Figure 23**. Also evident in **Figure 23** is a limiting CR beyond which velocity has little effect, because the relevant anodic and cathodic processes are activation controlled. In contrast, the passive films that form on chromium-containing alloys are less vulnerable to

relatively low acid velocities away from conditions close to transitions to activity or transpassivity and the films that form on silicon-containing alloys, as in the case of stainless steels, are relatively resistant to acid velocity.

#### 2.23.4.2 Performances of Nickel Alloys

The compositions of some wrought nickel alloys that are significant for sulfuric acid applications are summarized in **Table 2**. The substantial nickel contents of all the alloys provide significant improvements in corrosion resistance relative to the iron-based alloys across most of the concentration range. The nickel–copper alloy 400 (N04400) can be used to handle weak- and medium-strength acids up to ~60% concentration (w/w) and ~95 °C in the absence of air and other oxidizing agents, but other materials are generally preferred and the alloy has no application in the strong acid concentration range. The B family of alloys show the greatest resistances across a wide range of temperatures and concentrations in the pure acid, exemplified by alloy B-2 (N10665) in **Figure 24**, but in practice are very vulnerable to the presence of even small quantities of oxidizing agents that can promote corrosion at unacceptable rates, and therefore, great care is needed in their application.

The most versatile alloys for handling sulfuric acid are the passivable nickel–chromium and nickel–chromium–molybdenum alloys that range from alloy 825 (N08825), which bridges the gap to stainless steels, to the more nickel-rich 690 (N06690) and the

C family of alloys. The performances of alloys 825 (N08825), 625 (N06625), G (N06007), and C-276 (N10276), shown in [Figure 25](#), bear comparison with the equivalent performances of the more highly alloyed stainless steels that are exemplified in [Figures 13 and 14](#). The leanest alloy 825 (N08825) offers little advantage over the 904L/26–5MO/27–7MO grades of stainless steel. The C family of alloys, exemplified by alloy C-276 (N10276) in [Figure 25](#), provides the most consistent resistance to temperature in

weak and medium-strength acids into the strong acid concentration range, and their performances are generally enhanced by the presence of oxidizing agents. However, they are vulnerable to the presence of chlorides, particularly in more concentrated acids at higher temperatures.<sup>2,4</sup>

A number of proprietary alloys have found significant usage for niche applications, particularly in relatively hot, concentrated acids. Lewmet alloys 55 and 66, and Ilium B are cast alloys containing relatively high levels of chromium and copper, and in the case of Ilium B, a significant level of silicon, and they are used for pumps and valves. Alloy D-205 is a silicon-containing nickel alloy that was developed to withstand acids in the concentration range of 93–99% (w/w) at temperatures of 90 °C and above, depending on acid strength, and which is more easily formed in thin sections than the equivalent stainless steels for components such as heat exchanger plates.

## 2.23.5 Other Metals and Alloys

### 2.23.5.1 Aluminum and Aluminum Alloys

Aluminum and its alloys have limited resistance to sulfuric acid other than in weak acids at relatively low temperatures and find no significant applications as constructional materials. However, thick, porous coatings can be formed on aluminum and some of its

**Figure 25** Isocorrosion charts ( $0.13 \text{ mm year}^{-1}$ ) for Ni-Cr-Mo alloys in sulfuric acid. Adapted from *The Corrosion Resistance of Nickel-Containing Alloys in Sulphuric Acid and Related Compounds*; Corrosion Engineering Bulletin 1, The International Nickel Company, 1983.

alloys by anodic polarization to voltages up to  $\sim 25 \text{ V}$  in 5–10% sulfuric acid. These are of commercial significance for corrosion protection and decoration in architectural and other applications and are the subject of a separate chapter in this book.

### 2.23.5.2 Copper and Copper Alloys

Copper is relatively noble and does not normally displace hydrogen from acid solutions and thus has a relatively good resistance to sulfuric acid in nonoxidizing conditions. However, its resistance is reduced significantly in the presence of air or other oxidizing agents, not least its own corrosion product,  $\text{Cu}^{2+}$ , which can stimulate corrosion autocatalytically. The brasses are vulnerable to dezincification in sulfuric acid solutions. The tin, silicon, and aluminum bronzes have useful resistances in weak and medium-strength acids at moderate temperatures,<sup>2,4</sup> but, in general, applications for copper and its alloys in sulfuric acid are limited.

### 2.23.5.3 Titanium and Titanium Alloys

Titanium and its alloys are dependent on passive film formation to resist corrosion in sulfuric acid. One of the conditions for film formation, viz. the availability of a cathodic process to elevate the corrosion potential above the potential for passive oxide formation, is satisfied across the concentration range, even in weak acids, because this potential is below the hydrogen evolution potential. However, film formation also

depends on the availability of free water, the concentration of which is progressively limited in concentrated acids and in weak and medium-strength acids, the solubility of the passive film increases with the concentration and temperature and dominates performance. It has been shown that the protection afforded by the film depends on the conditions under which it forms, in particular the formation rate.<sup>36</sup> As a result, the resistances of titanium and its alloys are limited to relatively weak acids.

**Figure 26(a)** shows isocorrosion curves ( $0.13 \text{ mm year}^{-1}$ ) for commercially pure titanium (ASTM grade 2, R50400), a titanium–nickel–molybdenum alloy (ASTM grade 12, R53400), and a titanium–palladium alloy (ASTM grade 7, R52400) in naturally aerated sulfuric acid. Evidently, pure titanium is restricted to concentrations below  $\sim 5\%$  (w/w) even at ambient temperatures. Alloying with palladium significantly improves the corrosion resistance at lower temperatures but, as shown in **Figure 26(b)**, not much beyond  $\sim 5\%$  (w/w) at the boiling temperature. The improvements in corrosion resistance of ASTM grade 7 (R52400) arise from the well-established cathodic modification effects of palladium on promoting and sustaining the passivity of titanium, described elsewhere in this book.

Oxidizing agents in the acid, such as dissolved oxygen, chlorine, nitric and chromic acids, and metal cations in higher oxidation states, such as  $\text{Fe}^{3+}$  or  $\text{Cu}^{2+}$ , also promote significant increases in corrosion resistance by promoting and sustaining passivity. Some of the largest, titanium-clad process vessels ever

**Figure 26** (a) Isocorrosion chart (0.13 mm year<sup>-1</sup>) for ASTM grades 2 (commercially pure Ti), 7 (Ti 0.12–0.25%Pd) and 12 (Ti 0.6–0.9%Ni 0.2–0.4%Mo) alloys in naturally aerated sulfuric acid (b) corrosion rates of Ti and Ti 0.2%Pd alloy in boiling acid. Adapted from *Handbook of Corrosion Data*; ASM International, 1995.

constructed are used for the acid leaching of ores to recover gold, nickel, and other metals, involving exposure to several % (w/w) sulfuric acid in the presence of significant partial pressures of oxygen at temperatures as high as 200–250 °C.<sup>37</sup> However, even the temporary absence of oxidizing agents can result in a loss of passivity and a risk of very high CRs, and this inevitably limits the wider application of titanium and its alloys in sulfuric acid applications.

#### 2.23.5.4 Lead and Lead Alloys

The lead–sulfuric acid system is the basis of the ubiquitous lead-acid accumulator battery in which lead electrodes are exposed to acid in the concentration range of 27–39% (w/w) when fully charged. As a result, the prevailing anodic and cathodic processes have been studied intensively. The anodic reaction during discharge is the dissolution of lead in the divalent state followed by the precipitation of lead sulfate on the anode, and this is also the mechanism via which lead and its alloys resist corrosion in sulfuric acid. The effects of temperature and concentration on the CR of lead in stagnant sulfuric acid are shown in Figure 27.<sup>38</sup> Evidently, lead is very resistant to corrosion at temperatures up to boiling in 50% (w/w) acid and ~80 °C in 85% (w/w) acid, beyond which the film dissolves at rates that increase progressively. However, as in the case of the equivalent

films on steels, sulfate films on lead are vulnerable to erosion and abrasion resulting in excessive rates of attack, particularly at conditions close to the boundary for acceptable corrosion. For this reason, lead has often been used as a corrosion resistant membrane behind acid-resistant brick linings that separate the lead from any potentially damaging velocity and abrasion effects.

Historically, lead and its alloys found significant application in equipment for the manufacture and storage of sulfuric acid, but its use has declined because of its relatively poor mechanical properties, and health and toxicity concerns, resulting in a shortage of skilled craftsmen.

#### 2.23.5.5 Zirconium and Zirconium Alloys

Zirconium and its alloys are similar to titanium and its alloys in their dependence on passive film formation to resist corrosion in sulfuric acid. The key difference is that the passive films on zirconium and its alloys are much less soluble in sulfuric acid across the weak and medium-strength concentration range. The effects of concentration on the anodic polarization behavior of zirconium near the boiling point are shown in Figure 28(a).<sup>39</sup> Evidently, at concentrations below 20% (w/w), zirconium shows no active region and no tendency to transpassive breakdown at potentials significantly above 1 V relative to the saturated

**Figure 27** Effects of temperature and concentration on corrosion rates of lead in sulfuric acid. Adapted from Hofmann, W. *Lead and Lead Alloys: Properties and Technology*; Vibranos, G., Ed.; Springer-Verlag, 1970.

**Figure 28** Effects for zirconium in sulfuric acid of (a) concentration (% w/w) on anodic polarization behavior near the boiling point. Adapted from Yau, Te-Lin *Understanding Corrosion Behaviour From Electrochemical Measurements*; Paper 04227, Corrosion 2004; NACE International, 2004 (b) temperature and concentration on corrosion rate. Adapted from *Handbook of Corrosion Data*; ASM International, 1995.

calomel electrode (SCE). At higher concentrations, transpassive breakdown behavior is exhibited at potentials that reduce with increasing concentration and at 70% (w/w) concentration and beyond, zirconium reverts to active behavior with no evidence of stable passivity.

This behavior is reflected in the performance of commercial purity zirconium (Zr702, R60702) in

sulfuric acid as a function of concentration and temperature, which is summarized in [Figure 28\(b\)](#).<sup>40</sup> Evidently, at concentrations up to 20% (w/w), zirconium resists attack at temperatures well above the boiling point, beyond 200 °C. The limiting temperature for passivity decreases as the concentration increases beyond 20% (w/w) but remains above the boiling point in pure acid up to >60% (w/w).

In 70–80% (w/w) acid, the limiting temperature for passivity falls off rapidly with increasing concentration due to the formation of nonprotective zirconium sulfate films. **Figure 28(b)** indicates that the resistance of zirconium welds to >55% (w/w) acid is marginally lower than for parent material due to the presence and morphology of second-phase particles, related to tin content, but appropriate heat treatment can restore the corrosion resistance of weld metal. The performances of the commercial grades containing tin (Zr704, R60704) and niobium (Zr705, R60705) are broadly similar, except in the near boiling region above ~60% (w/w) acid concentration, where Zr702 outperforms Zr704 and Zr705.

The polarization curves in **Figure 28(a)** suggest that zirconium and its alloys may be vulnerable to the presence of oxidizing agents in higher concentration acids that might elevate the potential above the corresponding transpassive breakdown potential. In practice, zirconium is relatively tolerant to oxidizing agents over most of its useful concentration range but in >60% (w/w) acid, becomes sensitive to the presence of oxidizing agents.<sup>41</sup> Chlorides can also accelerate CRs if oxidizing agents are present, and zirconium and its alloys are acutely sensitive to the presence of even small quantities of fluorides in acids of all strengths.

Zirconium is vulnerable to stress corrosion cracking in 64–69% (w/w) sulfuric acid, the mechanism and remedies for which have been described elsewhere.<sup>42</sup>

### 2.23.5.6 Tantalum and Tantalum Alloys

Tantalum forms very stable, oxide films in sulfuric acid across the concentration range. For example, films formed galvanostatically in 95% (w/w) acid at 25 °C continue to thicken to support an applied potential of ~50 V before breaking down.<sup>43</sup> It is thus not surprising that tantalum (R05200) has an exceptional corrosion resistance to sulfuric acid, as illustrated by the CR data in **Figure 29**, which shows that tantalum has exceptionally low CRs at concentrations up to 98% (w/w) acid at temperatures up to ~150 °C and corrodes very slowly in 98% (w/w) acid at temperatures up to ~200 °C. However, tantalum is much less resistant to fuming acids, as illustrated by the data for oleum in **Figure 29**.<sup>42</sup> Long-term tests have suggested temperature limits for unalloyed tantalum of 200 °C and 150 °C for acid concentrations of 96 and 97% (w/w), respectively, and temperature limits for the 2.5% tungsten alloy (R05252) of

**Figure 29** Effects of temperature on corrosion rates of tantalum in 98% (w/w) sulfuric acid and oleum. Adapted from *Handbook of Corrosion Data*; ASM International, 1995.

210 °C and 175 °C for acid concentrations of 96 and 97.5% (w/w), respectively. The same tests have suggested that the tungsten alloy has superior resistance to hot, concentrated acids that contain oxidizing agents such as nitrates.<sup>44</sup>

A guide to the uniquely wide ranging corrosion resistance of tantalum and its alloys to sulfuric acid is illustrated by the test data in **Figure 30** for a range of metals and alloys in boiling acids across the concentration range up to 80% (w/w). It is clear that only tantalum and its alloys provide acceptable resistance across the full concentration range tested.

### 2.23.6 Nonmetallic Materials

Given the limitations of most classes of alloy that might be considered for handling sulfuric acid, and the high cost of the more resistant materials, such as nickel, zirconium, and tantalum alloys, it is inevitable that nonmetallic materials play significant roles in sulfuric acid applications. The application of these materials is covered in more detail in the relevant chapters in this book, but the more significant materials are as follows:

#### 2.23.6.1 Organic Materials

Concentrated sulfuric acid is a strong oxidizing and dehydrating agent, and hence, organic materials have inevitable performance limitations in concentrated and hot acids.

**Figure 30** Effects of concentration on corrosion rates in boiling sulfuric acid. Adapted from Rebak, R. B.; Crook, P. *Influence of Alloying Elements, Temperature and Electrolyte Composition on the Corrosion Behaviour of Nickel-based Alloys*, Paper 00499, Corrosion 2000; NACE International, 2000.

In relation to chemical compatibility, the major thermoplastics perform broadly as follows:

1. Polyethylene (PE), depending upon its molecular weight, can resist weak and medium-strength sulfuric acid at temperatures up to  $\sim 60^\circ\text{C}$ , depending on concentration and concentrated acids at ambient temperature.
2. Polypropylene (PP) is more resistant than PE and can tolerate weak acids up to  $\sim 90^\circ\text{C}$ , and medium-strength and concentrated acids at temperatures that reduce with increasing concentration.
3. Polyvinyl chloride (PVC) and chlorinated polyvinyl chloride (CPVC) resist concentrated acids at ambient temperatures and medium and weak acids at temperatures that increase as the concentration decreases.
4. Fluoroplastics are very resistant to sulfuric acid, depending upon their degree of fluorination. The highly fluorinated materials polytetrafluoroethylene (PTFE), fluorinated ethylene propylene (FEP), and perfluoroalkoxy (PFA) are resistant to all concentrations of sulfuric acid and oleum at temperatures up to at least  $200^\circ\text{C}$ . The less highly fluorinated materials ethylene chlorotrifluoroethylene

(ECTFE) and ethylene tetrafluoroethylene (ETFE) resist up to 98% (w/w) acid at temperatures up to  $\sim 150^\circ\text{C}$ . Polyvinylidene fluoride (PVDF) also resists up to 98% (w/w) acid but at temperatures that vary from  $\sim 120^\circ\text{C}$  at the lower end of the concentration range to  $\sim 50^\circ\text{C}$  at 98% (w/w) acid.<sup>2,4</sup>

In practice, chemical compatibility is but one factor that determines the suitability or otherwise of a thermoplastic material for a specific application. Other factors, such as mechanical and fabrication properties, thermal expansion characteristics, permeation properties, etc., are significant design considerations. In practice, except for small scale equipment, thermoplastics are used more commonly as linings on stronger substrates rather than in solid form, because of reliability and integrity concerns.

The more common natural and synthetic elastomers are unsuitable for concentrated acids. Thus, butyl rubber and neoprene are generally limited to weak and medium-strength acids, but chlorosulfonated PE elastomers (e.g., Hypalon) can be used in concentrated acids. Some grades of fully fluorinated elastomers (e.g., some Kalrez grades) can be used in

concentrated acids and even oleum, depending on the filler materials.

The common glass reinforced polyester and vinyl ester resins find significant use in the storage and handling of weak acids up to temperatures of  $\sim 90^{\circ}\text{C}$  and medium-strength acids up to lower temperatures, depending on the acid strength. However, these materials are not suitable for concentrated acids.

Thin paint coatings are unsuitable for the protection of substrates that would corrode at significant rates if exposed. However, some high-performance coatings, for example, heat-cured phenolic coatings, are used to prevent contamination of concentrated acids that are stored in steel containers.

### 2.23.6.2 Inorganic Materials

Borosilicate glass is highly resistant to acids across the concentration range up to temperatures well beyond their boiling points and solid- or glass-lined equipment finds significant use for handling sulfuric acid.

Impervious graphite, filled with impregnants such as phenolic resins or PTFE, finds significant use in heat exchange duties and is resistant to all but the most oxidizing conditions at temperatures well beyond boiling. Silicon carbide also has an excellent sulfuric acid resistance and has been used in heat exchange duties.

Acid-resistant brick linings on steel are widely used to handle sulfuric acid. Below  $\sim 70\%$  (w/w) concentration, corrosion-resistant membranes are required behind the brick, which can be metallic, such as lead, or nonmetallic, such as fluoroplastic linings or asphaltic or other coatings. In concentrated acids, the bricks can be used directly onto steel, although in practice, fluoroplastic or other membranes are often installed. Carbon bricks find occasional use in very hot, concentrated acid duties.

### Glossary

**18/13/1** A niobium-stabilized stainless steel used in UK nuclear reprocessing plant, conforming approximately to the top end of the AISI 347 specification range.

**End grain** The cross-section perpendicular to the hot-working direction of a fabricated component.

**Grain dropping** Dislodgement of metal grains as they are undermined by intergranular

corrosion. Dropped stainless steel grains have the appearance of fine soot.

**Magnox** A magnesium alloy containing 0.8% aluminum, used to clad uranium metal fuel for CO<sub>2</sub>-cooled Magnox reactors.

**NAG 18/10L** A proprietary stainless steel used in UK nuclear reprocessing plant, similar to AISI 304L but with tighter control of residuals.

**Radiolysis** Chemical change resulting from the absorption of ionizing radiation.

**R-SUS 304ULC** A proprietary stainless steel used in Japanese nuclear reprocessing plant. Similar to NAG 18/10L.

**20Cr25Ni1Nb** A proprietary stainless steel used in UK Advanced Gas-Cooled Reactor fuel.

**Uranus 65** A proprietary stainless steel, conforming approximately to AISI 310L, but with added niobium. Used in UK and French nuclear reprocessing plant.

## Abbreviations

**AISI** American Iron and Steel Institute

**AR** As-received

**Gy** Grays (unit of absorbed radiation dose;  
1 Gy = 1 J kg<sup>-1</sup>)

**mpy** Thousandths of an inch per year

**M** Molar or metal

**NAG** Nitric acid grade

**SCC** Stress corrosion cracking

**ss** Stainless steel

## Symbols

**E** Electrode potential

**i** Current density

**V<sub>SCE</sub>** Electrode potential, volts with respect to the Standard calomel electrode

**X(Y)** Element X present in valency state Y; for example, Cr(VI) is Cr<sub>2</sub>O<sub>7</sub><sup>2-</sup> or CrO<sub>4</sub><sup>2-</sup>

## 2.24.1 Uses of Nitric Acid

Nitric acid is used in salt formation, preparation of organic nitrates and nitro compounds, and oxidation of organic compounds.<sup>1</sup> Major applications include the production of agricultural fertilizers and reprocessing of nuclear fuels.

## 2.24.2 Chemical Attack by Nitric Acid

### 2.24.2.1 Pure Nitric Acid

At greater than about 96–97% concentration, HNO<sub>3</sub> chemistry is dominated by the NO<sub>2</sub><sup>+</sup> ion. The acid undergoes no proton transfer to water molecules and it cannot be considered as an acid in the protionic sense at this concentration.<sup>2</sup>

The initial electron transfer reaction with a metal, M:

leads to the overall reaction

with nitrates produced at the metal surface.<sup>2</sup>

The reaction of some metals with pure HNO<sub>3</sub> is given in Table 1.

There is no correlation between apparent reactivity and position of the metal in the periodic table. In some instances, there is evidence of cohesive film formation (e.g., Ca) while some metals are either inert (e.g., Pt) or form protective oxide films (e.g., Al).

### 2.24.2.2 Aqueous Nitric Acid

In practice, most nitric acid corrosion occurs in aqueous mixtures of <96% concentration.

#### 2.24.2.2.1 Base metals in aqueous nitric acid

These generally dissolve extremely rapidly to form nitrates, cathodically discharging hydrogen, which reacts with the nitric acid to give compounds such as ammonia, ammonium nitrate, hydroxylamine nitrate, nitrogen, and nitrous oxide.<sup>3</sup>

#### 2.24.2.2.2 Noble metals in aqueous nitric acid

The dominant cathodic reaction in this case is the reduction of the nitrate ion. This is a complex process, proceeding via an autocatalytic mechanism involving a charge transfer reaction and various chemical reactions leading to the regeneration of the active species (nitrous acid). The autocatalytic nature of the reaction can readily be demonstrated by simple observation of the corrosion rate of copper, for example, in nitric acid solutions: the rate, as evinced by NO<sub>x</sub> evolution, is initially low, but accelerates rapidly if the copper is placed in contact with a surface, thus forming a crevice, which traps the nitrous acid generated, or if a little nitrite is added

**Table 1**     Reaction of pure HNO<sub>3</sub> with metals

<i>Solution complete within</i>			<i>Evidence of inhibition by film</i>	<i>No evidence of reaction</i>
<i>1 day</i>	<i>1 week</i>	<i>1 month</i>		
Mg	Cr powder	Fe	Ca	Be
Sc		Mn	Cu	Al
V	Ni		Ag	Ti
Co	Cd		Bi	Pt
Zn	U			Sn
Hg

to the solution; conversely, the rate is retarded by agitation or stirring of the acid, which displaces the nitrous acid generated, or by the addition of a chemical such as urea, which impedes the autocatalytic reaction by destroying nitrous acid.<sup>3</sup>

Two basic mechanisms have been proposed: one heterogeneous<sup>4</sup> leading to NO<sub>2</sub> formation and one homogeneous<sup>5</sup> leading to NO. Both mechanisms have been shown to be consistent with experimental data collected over different potential ranges.<sup>6</sup> More recently, a modified mechanism has been suggested, which results in two limiting cases, one applicable for low nitric acid concentrations (<8 M) leading to NO formation, the other for high nitric acid concentrations (>8 M) leading to NO<sub>2</sub>.<sup>7</sup> According to this scheme, the major species involved in the reduction of nitric acid at low overvoltages are nitrous acid (HNO<sub>2</sub>), NO, and NO<sub>2</sub>, and the charge transfer reaction is the reduction of HNO<sub>2</sub>:

The product of the overall cathodic reaction is HNO<sub>2</sub>, thus giving rise to autocatalysis:

Whatever the precise mechanism, the important point is that nitrate reduction is autocatalytic, being strongly affected by HNO<sub>2</sub>, NO, and NO<sub>2</sub>. Reactions [3] and [4] indicate that H<sup>+</sup> is required, but in all but the most dilute solutions it is the nitrate concentration that is important; thus, the addition of neutral nitrate salts to nitric acid generally increases the liquor corrosivity.

Iron can show both base and noble metal characteristics in its corrosion reactions. It is attacked at an increased rate in crevices, but its corrosion products include nitrous oxide, ammonia, and nitrogen as well as nitrogen dioxide and nitric oxide. In concentrated acids of >~40%, after an initial reaction, iron

becomes passive (although this can be disrupted relatively easily, by agitation, for example), whereas in dilute acids, reactions are rapid.<sup>8</sup>

#### 2.24.2.2.3 Passive metals

Highly reactive metals such as chromium, titanium, hafnium, niobium, and zirconium rapidly form thin insoluble surface oxides in air. These films may grow slightly on immersion in oxidizing acids, but then prevent further corrosion or reduce it to negligible rates in a wide range of nitric acid conditions. These metals or their alloys, as in the case of stainless steels, where alloying of iron with chromium confers much greater passivity, are the most important class of metals for the industrial handling of nitric acid.

This behavior is illustrated for stainless steels in Figure 1.<sup>9</sup> The polarization curve shows three distinct regions of active, passive, and transpassive corrosion. The effect of temperature on the anodic reaction is important, as demonstrated in Figure 2. Although increasing the temperature of stainless steel in nitric acid produces only a small increase in corrosion potential (due to augmentation of the cathodic reaction), the anodic polarization curve changes significantly; the passive region is effectively lost, and therefore, a small increase in potential leads to significantly increased corrosion. This is pertinent when considering the effect of oxidizing species or galvanic effects, which will therefore be more pronounced at high temperatures (see Sections 2.24.4.7 and 2.24.5.4.1).

### 2.24.3 Materials for Nitric Acid Containment

The primary materials used for nitric acid environments are stainless steels, titanium, and zirconium. Aluminum can also be used in some circumstances. The austenitic stainless steel, AISI 304L, and its

**Figure 1** Anodic polarization of stainless steel in 1 M nitric acid at room temperature. Reproduced from Kain, V.; Shinde, S.; Gadiyar, H. J. *Mater. Eng. Perform.* **1994**, *3*, 699–705, with permission from ASM International.

**Figure 2** Effect of temperature on polarization behavior of NAG 18/10L stainless steel in 8M nitric acid (measured by step-wise potentiostatic polarization, 10 mV steps each of 1 h duration). Takeuchi, M.; Whillock, G. O. H. BNFL unpublished work.

variants are now the most commonly used, although much early plant has been made from stabilized austenitic steels such as AISI 321, AISI 347, and 18/13/1. In more oxidizing conditions, higher alloy steels such as AISI 310L or possibly high Si stainless may be preferred. In the most aggressively oxidizing conditions, titanium, zirconium, niobium, hafnium, or tantalum may be used. In the past, titanium has

**Table 2** Indicative corrosion rates of various metals subject to testing in boiling 65% nitric acid

<sup>c</sup>Sensitized.

<sup>d</sup>The high corrosion rate is due to the test conditions employed (see [Section 2.24.3.2](#)).

Source: Quayle, B. E. BNFL unpublished work.

been the most widely used, but the use of zirconium in preference has increased in recent years. The others find only occasional use, despite their excellent corrosion resistance, because of high cost and fabrication difficulties. [Table 2](#) provides indicative corrosion rates for some of these metals.

### 2.24.3.1 Stainless Steels

The industrial use of stainless steel for nitric acid containment seeks to ensure that it operates in the passive regime where corrosion rates are typically  $<0.01 \text{ mm year}^{-1}$ . However, it is also possible to operate stainless steel plant successfully for extended periods in the potential regime between passivity and full transpassivity where intergranular corrosion occurs and the corrosion rate is significant (see [Section 2.24.4.1](#)). In practice, all stainless steel plant handling hot nitric acid operates in the intergranular corrosion regime.

Corrosion rates show Arrhenius behavior over a large range of acid concentrations and temperatures, as illustrated in [Figure 3](#), indicating that electron transfer is the rate-determining step in the corrosion mechanism.

Austenitic stainless steels are the most widely used for nitric acid containment. Reasonable or good nitric acid resistance can be achieved with ferritic, super ferritic, and ferritic–austenitic (duplex) steels, but they are generally less resistant than the austenitics, and factors such as compositional variation, heat treatment, and welding can lead to reduction in corrosion resistance.<sup>11</sup> Ferritic stainless steels with  $>14\%$  Cr resist corrosion in nitric acid at room temperature, and high Cr/Mo ferritics such as 26Cr1Mo, and 29Cr4Mo resist nitric acid up to 65% boiling. Duplex

stainless steels have similar resistance to ferritics, but the ferritic phase can be preferentially attacked.<sup>11</sup>

AISI 300 series stainless steels (i.e., austenitic) are adequate for a wide range of applications up to about 70% acid concentration. AISI 304L is now commonly used and improvements in its performance can be achieved by improved manufacturing processes to reduce elements such as Si, P, S, and C, as illustrated

**Figure 3** Corrosion rate of stainless steel (R-SUS 304ULC) as functions of temperature and nitric acid molarity. Reproduced from Onoyama, M.; Nakata, M.; Hirose, Y.; Nakagawa, Y. In *Proceedings of the RECOD'91, Japan Atomic Industrial Forum: Japan, 1991*; Vol II, pp 1066–1071.

in **Figure 1**. Here, a nitric acid grade version of 304L shows improved corrosion resistance in the passive and lower transpassive region. However, it is doubtful whether significant corrosion differences persist under more aggressive oxidizing conditions where higher chromium steels such as 310L may be required.<sup>12</sup> Alternatively, in extremely oxidizing conditions stainless steels containing Si at  $>\sim 4\%$  (e.g., Uranus S1N) may find application, although such steels are more problematic to join because some ferrite needs to be maintained in the welds to avoid cracking.<sup>13</sup>

### 2.24.3.2 Titanium

Titanium has a high corrosion resistance to a range of nitric acid concentrations, provided there is sufficient concentration of dissolved titanium or other oxidizing ions present.<sup>14,15</sup> In the absence of such dissolved ions, corrosion rates can reach or exceed  $1 \text{ mm year}^{-1}$ . Hence, corrosion rates in the vapor regions of operating plant handling condensing nitric acid, where continuous washing prevents the accumulation of dissolved titanium, can be significant even though the metal below liquor is unaffected. Titanium is accordingly no longer recommended for use in condensing nitric acid. Owing to the sensitivity of titanium corrosion rates to the presence of dissolved titanium, account must be taken of the suppressing effect of corrosion product accumulation when assessing corrosion rate data. The susceptibility of titanium to corrosion in pure acid can be mitigated by alloying with tantalum; at  $>5\%$  Ta, corrosion is significantly reduced.<sup>14</sup> These effects are illustrated by the corrosion data in **Table 3**.

**Table 3** Effect of test conditions on the corrosion rate of titanium and titanium–tantalum alloys

Metal	Nitric acid concentration plus additions	Liquor renewal (h)	Corrosion rate ( $\text{mm year}^{-1}$ )	Source
Ti	6 M	14	0.6	(a)
	6 M	65	0.43	(b)

<sup>a</sup>Quayle, B. E. BNFL unpublished work.

<sup>b</sup>Shimogori, K.; Satoh, H.; Kamikubo, F. In *Titanium Science and Technology*; Proceedings of the 5th International Conference on Titanium, Munich, Germany, 10–14 Sept; 1984; Lutherling, G., Ed., Vol. 4, pp 1111–1114.

<sup>c</sup>Takamura, A.; Arakawa, K.; Moriguchi, Y. In *The Science Technology and Application of Titanium*; Jafee, R. I., Promisel, N. E., Eds.; Pergamon Press: Oxford, 1970; pp 209–216.

Titanium can also be susceptible to enhanced corrosion in both weld metal and heat-affected zones. This has generally been attributed to the redistribution of iron impurities during the welding operation so that the iron originally present in discrete stringers or well-distributed particles is deposited on grain boundaries either as iron–titanium intermetallic compounds or as  $\beta$ -phase. The formation of a continuous grain boundary network can lead to intergranular corrosion and grain dropping in certain conditions. This is likely to become more significant in marginally passive environments where these iron-rich phases may become soluble. To avoid this problem, it is now recommended that iron levels in titanium are specified to be  $<0.05\%$ .<sup>16</sup>

### 2.24.3.3 Zirconium, Niobium, Hafnium, and Tantalum

These materials are generally highly resistant to nitric acid corrosion (see Table 2), although operating experience of these materials is less extensive than that of titanium. There are no reported materials issues affecting corrosion performance, although stress corrosion cracking (SCC) of zirconium cannot be entirely discounted in extremely oxidizing conditions (see Section 2.24.4.4). In addition, zirconium is very susceptible to trace levels of fluoride ions (see Section 2.24.5.5). There have been no reported instances of enhanced vapor phase corrosion and they do not require the presence of dissolved ions to achieve passivity.

### 2.24.3.4 Aluminum

The corrosion rate of aluminum and its alloys is appreciable in all but very concentrated nitric acid, reaching  $3\text{--}5\text{ mm year}^{-1}$  at room temperature in 30% acid, whereas rates of  $<0.1\text{ mm year}^{-1}$  can be achieved in  $>85\%$  acid. This is illustrated in Figure 4<sup>17</sup>. The corrosion rate is strongly temperature dependent and increases with the level of copper impurity. However, a number of aluminum alloys containing magnesium silicon or manganese have corrosion rates comparable with those of pure aluminum in 98.5% acid.<sup>18</sup> As would be expected from its decreased corrosion resistance in dilute acids, aluminum corrodes more quickly where dilute acid condensates are formed above concentrated acids.<sup>19</sup> Hence, although aluminum can be suitable for room temperature storage of concentrated nitric acid, the vapor regions of storage vessels may undergo increased corrosion.

**Figure 4** Corrosion rate of various aluminum alloys as a function of nitric acid concentration and temperature. Reproduced from Singh, D. D. N.; Chaudhary, R. S.; Agarwal, C. V. J. *Electrochem. Soc.* **1982**, 129, 1869–1874, with permission from The Electrochemical Society.

## 2.24.4 Corrosion Mechanisms of Passive Metals in Nitric Acid

### 2.24.4.1 General Corrosion and Intergranular Corrosion

For stainless steels, full transpassivity occurs when the  $\text{Cr}_2\text{O}_3$ -based passive film becomes unstable in extremely oxidizing conditions, allowing corrosion to proceed by the formation of soluble  $\text{CrO}_3$ ; this occurs at  $\sim 1.0\text{ V}_{\text{SCE}}$ .<sup>20</sup> However, grain boundaries are more vulnerable to corrosion. This is largely due to impurities in the metal, with the segregation of silicon and phosphorus being particularly implicated.<sup>21,22</sup> The transpassive corrosion process therefore proceeds primarily by grain boundary dissolution, but is manifest as general corrosion owing to grain dropping. Owing to the high corrosion rates encountered, stainless steels are unsuitable for use in extremely oxidizing conditions where transpassive corrosion occurs.

In the potential band between full passivity and transpassivity (i.e., between  $\sim 0.9$  and  $\sim 1.0\text{ V}_{\text{SCE}}$ ), intergranular corrosion occurs. This is the principal mechanism affecting stainless steels handling nitric

**Figure 5** Morphology of intergranular corrosion of 18/13/1 stainless steel exposed to 8 M nitric acid containing  $25 \text{ g l}^{-1}$  Fe(III) at  $100^\circ\text{C}$ . The sections show penetration into (a) plate, (b) side and (c) end surfaces after 340 h exposure. (d) Shows end grain pitting after 1000 h exposure. Magnification: (a)–(c)  $\times 360$ ; (d)  $\times 150$ . Dunnett, B. F. BNFL unpublished work.

acid solutions which are too oxidizing for the maintenance of passivity. Intergranular attack increases significantly if the steel has become sensitized by heat treatment,<sup>23</sup> but sensitization is not a prerequisite, intergranular corrosion occurring in the fully solution-annealed condition even in very clean stainless steels providing potentials in excess of  $\sim 0.9 V_{\text{SCE}}$  are achieved in hot solutions. The intergranular corrosion rate can be strongly anisotropic, depending on the orientation of the exposed face to the underlying microstructure (see also Section 2.24.4.2). Figure 5 illustrates this. The effects tend to be less pronounced in modern ultraclean stainless steels, but are still evident.

General corrosion curves derived for stainless steels from weight loss are broadly characterized by two regions, as illustrated in Figure 6.<sup>24</sup> In the early stages, grain boundaries are etched, but no grains are lost, and weight loss is by chemical dissolution only. The apparent corrosion rate rises as the grain boundaries are penetrated more deeply because a greater area of metal is opened to corrosion. As time progresses, grains begin to drop out of the metal surface as their boundaries are completely corroded. Eventually, a relatively stable corrosion rate is reached, which is a combination of chemical dissolution and grain dropping. For AISI 304L stainless steel and related steels, grain dropping accounts for only  $\sim 25\%$  of the total metal loss, chemical dissolution of the grain boundary regions accounting for the rest.<sup>25</sup> It is therefore important in deriving corrosion

**Figure 6** Effect of immersion time on the corrosion rate of 18/13/1 stainless steel in 8 M nitric acid containing  $25 \text{ g l}^{-1}$  Fe(III) at a solution temperature of  $100^\circ\text{C}$ . Reproduced from Dunnett, B. F.; Whillock, G. O. H. *Corrosion* **2003**, 59, 274–283, with permission from NACE International.

rates from analysis of dissolved species to allow for grain dropping.

Corrosion rates derived from weight loss averaged over the specimen area will tend to be underestimated in the early stages of corrosion. In practice, the corrosion curve is an artifact of the measurement process; if measurements of penetration are made, then it is found that the rate of penetration is constant and corresponds to the corrosion rate derived from weight loss once steady grain dropping is established.<sup>24</sup> The time to reach this state depends on the corrosion resistance of the steel, its grain size, and the corrosivity of the medium.

This problem can be addressed either by numerical models to predict the long-term rate from short-term data<sup>26,27</sup> or by pre-corroding test samples in aggressive media to establish grain dropping before reverting to the required test media.<sup>24,28</sup> The validity of numerical models is still to be fully established. Pre-corrosion appears to be a valid method, although it appears that care needs to be taken in selecting the pre-corrosion conditions, otherwise reasonably prolonged testing in the liquor of interest may be required in order to establish the true corrosion rate. In practice, it is found that the overall metal loss by intergranular corrosion is fairly uniform even in plants operating with relatively aggressive environments. Hence, extrapolation of the steady-state corrosion rate to predict plant life is valid, provided there are no localized mechanisms acting, such as crevice/underdeposit corrosion (see Section 2.24.4.3).

Intergranular corrosion in stainless steels can be suppressed by alloying with silicon.<sup>13</sup> At  $>4\%$  Si, intergranular corrosion is suppressed, but general

corrosion rates at most nitric acid concentrations are higher at least in the early stages of corrosion compared with the equivalent AISI 300 series stainless steel. In particular, high Si stainless steels show a significant improvement in corrosion resistance in super-azeotropic solutions. However, welding of these alloys can be problematical; ferrite needs to be maintained in the welds to avoid cracking, and welds can be susceptible to enhanced corrosion.<sup>13</sup>

Intergranular corrosion of other passive metals such as zirconium and tantalum has not been reported. Of these metals, only titanium shows a transpassive breakdown in normal operating conditions, although a form of transpassivity (breakaway oxidation) can be induced in zirconium and its alloys under extreme conditions (in excess of  $\sim 2 V_{SCE}$ ).<sup>29</sup> Titanium can also exhibit intergranular corrosion at welds; this propensity tending to be associated with the presence of  $\beta$ -phase (see Section 2.24.3.2).

#### 2.24.4.2 End Grain Corrosion

The rate of intergranular penetration depends on the orientation of the exposed face to the underlying microstructure. In general, the corrosion rate increases in the order: plate < side < end (see Figure 5). The effects of end grain corrosion are clearly seen in boiling nitric acid testing (the Huey test, see Section 2.24.6) if specimens are cut so as to vary the percentage of exposed end grain in a susceptible material. Figure 7 shows an example, clearly demonstrating a significant effect for end grain fractions exceeding  $\sim 10\%$ .

In addition to this pronounced effect of end grain on the general corrosion rate, localized pitting-like

**Figure 7** Effect of end grain fraction on the corrosion rate obtained from successive 48 h test periods of 18/13/1 stainless steel in boiling 65% nitric acid. Quayle, B. E. BNFL unpublished work.

attack can develop parallel to the hot-working direction. This is known as ‘end grain’ or ‘tunneling’ corrosion. Figure 8 shows an example. Older stabilized steels appear to be most vulnerable, and the phenomenon is extremely variable even within the same grade of steel. However, extremely clean stainless steels such as R-SUS 304ULC and Uranus 65 also exhibit end grain pitting.<sup>30,31</sup> In such steels, the mechanism is considered to be a consequence of the exposure of segregated material in the original ingot, which has been distributed, producing bands with more susceptible grain boundaries.<sup>31</sup> In stabilized steels, stringers of magnesium sulfide and precipitates of niobium or titanium carbide mark out the regions of maximum segregation as they solidify late from the melt. The outer regions of the ingots solidify first, and hence contain little impurity segregation conferring superior corrosion resistance to the as-formed plate surface.

In practice, end grain corrosion of stainless steels is usually more of a problem for corrosion testing (see Section 2.24.6) than for operating plant where most end grain is welded over in pipe or plate joints, although issues can arise, for instance, with forgings where outcropping end grain can be present.

End grain corrosion of other passive metals has not generally been reported, although at least one instance on titanium is known.

#### 2.24.4.3 Crevice Corrosion

Although crevice corrosion is not widely reported in nitric acid, austenitic stainless steels are known to be susceptible to this mechanism in certain circumstances. One such example is corrosion testing of heat transfer surfaces, where corrosion focuses at

**Figure 8** End grain corrosion pits: 18/13/1 stainless steel stirrer paddle in nitric acid media. Green, D. S. BNFL unpublished work.

the mouth of the crevice on the external surface; for instance, under nucleate boiling at a heat flux of  $50 \text{ kW m}^{-2}$ , the depth of attack was twice that on the free surface.<sup>32</sup> Crevice corrosion appears to be possible only in more aggressive conditions, although indications of it have been found in isothermal tests at temperatures as low as  $90^\circ\text{C}$ ,<sup>33</sup> and in a nitric acid reboiler where corrosion rates increased from  $\sim 0.02$  to  $0.1 \text{ mm year}^{-1}$  on a heat transfer surface at  $\sim 90^\circ\text{C}$  in 12 M nitric acid. The mechanism may have several origins depending on the circumstances. For heat-transfer surfaces, the inhomogeneity provided by the crevice may simply lead to increased local surface temperatures, and hence increased local corrosion rate. The entrapment of stainless steel corrosion products is also possible (see [Section 2.24.5.4.1](#)), as is entrapment of  $\text{NO}_x$  species (see [Section 2.24.5.3](#)). The mechanism is oxidative rather than reductive in contrast to crevice corrosion brought about by chloride ions in water systems. The operation of a crevice in nitric acid systems is capable of adversely affecting the potential outside the crevice and increases the external corrosion rate. Care is therefore required in interpreting corrosion test data where the operation of a crevice is suspected.

Crevice corrosion has not been found on zirconium, titanium, or niobium under similar heat-transfer conditions in nitric acid. However, it has been recorded on zirconium in laboratory trials in acid contaminated by fluoride ions (see also [Section 2.24.5.5](#)) and also under cathodic polarization. It is probable that here the phenomenon is one of active corrosion in localized reducing conditions in the crevice. Crevice corrosion has not been reported for these metals in operating plant.

#### **2.24.4.4 Stress Corrosion Cracking**

Despite the intergranular nature of nitric acid attack of stainless steels, SCC of stainless steels in nitric acid is almost unknown. This is not due to a simple absence of stress, as postfabrication stresses at welds in austenitic stainless steels invariably approach yield. SCC is known to occur in weak nitric acid solutions and is facilitated by severe sensitization, the only known example in practice being intergranular SCC of irradiated stainless steel nuclear fuel cladding exposed to moist air, the corrosive agent being generated by nitrogen radiolysis (see [Section 2.24.5.6](#)). Slow strain rate testing reveals a link between the oxidizing power of the acid (i.e., the repassivation rate) and the metal rupturing rate (i.e., the strain rate).

SCC can occur in a critical regime where repassivation kinetics are such that the crack tip remains active; otherwise, crack blunting occurs at one extreme, with the absence of sufficient crack advancement at the other. The absence of SCC of stainless steel in stronger nitric acid solutions is accordingly attributed to too rapid repassivation rates relative to practically achievable strain rates.

SCC has also been induced in zirconium by slow strain rate testing.<sup>34</sup> However, this only occurs above the azeotrope and is therefore unlikely to be relevant other than in extremely oxidizing conditions. SSC of zirconium has not been reported in plant operating in nitric acid media.

#### **2.24.4.5 Corrosion Fatigue**

Normal air fatigue processes can be exacerbated in the presence of corrosive media, leading to corrosion fatigue. As in SCC, the process is complex, requiring conditions where a crack tip is continuously formed by fatigue and its propagation is accelerated by corrosion of the exposed metal. However, in passivating media, crack blunting is also possible.<sup>35</sup> Test rig data indicate that corrosion fatigue of stainless steel in nitric acid solutions is feasible in some circumstances, indicating that careful assessment may be required. However, corrosion fatigue in nitric acid plant appears not to have been encountered in practice.

There is no indication that zirconium or similar passive metals are susceptible to corrosion fatigue in nitric acid.

#### **2.24.4.6 Erosion Corrosion and Fretting Corrosion**

These mechanisms proceed in passive metals by removing the protective oxide film, leading to oxidation of the underlying reactive metal. Erosion corrosion requires the surface oxide to be scoured by a slurry of abrasive particles. The erosion corrosion rate depends on a variety of factors, including particle weight and sharpness, but is especially sensitive to particle velocity, with attrition rates typically increasing as  $(\text{velocity})^n$  where  $n$  is  $\sim 4$ .<sup>36</sup> A dynamic process ensues in which oxide is continuously removed and regrown. In metal–environment combinations where transient metal dissolution rather than simple repassivation of the scoured surface is possible, considerable enhancement of metal loss can occur.<sup>37</sup> For stainless steel abraded in water and in dilute nitric acid, the attrition rates have been found to be similar.

Although repassivation kinetics will differ for the two media, they will be rapid in both cases, and therefore, unless the erosion rate approached the repassivation rate, it is probable that full repassivation occurs at any given point before it is re-eroded, and therefore, no difference between the attrition rates in the two media is apparent.

It is, however, anticipated that a corrosive element will be more significant in erosion corrosion at transpassive potentials or where nitric acid is contaminated with halides (see [Section 2.24.5.5](#)) or other species, which lead to active dissolution of bared metal.

Fretting corrosion is possible when loaded surfaces move against each other in a corrodant. The process depends on loading, displacement, and cycling frequency and tends to be exacerbated if debris remains between the moving faces. Some studies in nitric acid show high attrition rates, but the relative contribution of wear and corrosion was not established and it is likely that similar processes and considerations to erosion corrosion apply.

#### 2.24.4.7 Galvanic Corrosion

Galvanic corrosion effects can occur in nitric acid in much the same way as other media. The consequence depends on the strength and direction of the resulting potential shift and may thus be beneficial, neutral, or deleterious to the half-couple of interest. Coupling with an actively corroding base metal, such as Magnox or uranium, tends to reduce the corrosion rate of stainless steels in hot nitric acid solutions. The behavior of aluminum is more complex, ranging from slight reduction in the corrosion rate of stainless steel in concentrated nitric acid solutions,<sup>38</sup> to marked enhancement in the stainless steel corrosion rate if the potential shift is sufficient to move stainless steel into its active region.<sup>39</sup> Caution is therefore needed in predicting the effect of coupling with base metals. Deleterious effects on stainless steel arise from coupling with lead<sup>40</sup> and noble metals, such as, for example, platinum catalyst fragments (fertilizer plant) or fission product solids rich in platinum metals (nuclear reprocessing plant). Less obvious is the effect of coupling stainless steels with markedly different chromium contents; coupling 18% and 25% Cr stainless steels (i.e., 304L and 310L) results in significant increase in corrosion rate of the former and decrease in corrosion rate of the latter in hot nitric acid solution. This arises because the corrosion potential of 25% Cr stainless steel is  $\sim 20$  mV higher than that of 18% Cr stainless steel in hot nitric acid, illustrating the

extreme sensitivity of corrosion rate to potential close to the onset of full transpassivity. In less oxidizing liquors, the effects of coupling noble metals to stainless steel are much less pronounced.<sup>41</sup>

Connections between other passive metals tend not to be problematic. For example, connections between stainless steel and zirconium plant have minimal effects on the corrosion of the junction below transpassivity; similarly, measurements on titanium/stainless steel couples show no enhanced corrosion.<sup>42</sup>

### 2.24.5 Factors Affecting Corrosion Processes in Nitric Acid

#### 2.24.5.1 Welding

Sensitization can occur during welding of stainless steels even if they are stabilized or low carbon grades, although the effects are much less pronounced than is the case for nonstabilized or high carbon steels. The formation of chromium-rich carbides at grain boundaries leaves chromium-depleted steel in their vicinity, creating a band of corrosion susceptible material running parallel to the weld but displaced a few millimetres from it. Such zones are more susceptible to intergranular corrosion in hot nitric acid, leading to heat-affected zone corrosion (weld decay). In niobium-stabilized stainless steels, the enhancement appears to be modest, amounting to at most  $\sim 10\%$  of the parent metal corrosion rate. [Figure 9](#) shows an example.

Knife-line corrosion is also possible in some circumstances. This is manifest as a sharp band of corrosion penetrating along the weld-parent metal interface where temperatures exceed  $1150^\circ\text{C}$  during

**Figure 9** Weld metal and heat affected zone corrosion: 18/13/1 stainless steel tube (steam-heated) in nitric acid media. Green, D. S. BNFL unpublished work.

the welding process. In most nitric acid solutions, this is an issue primarily for stabilized stainless steels such as AISI 321, since titanium carbides are susceptible to dissolution releasing carbon into solid solution, which then reacts with chromium, resulting in a chromium-deficient narrow band at the weld interface. Niobium-stabilized stainless steels such as AISI 347 and 18/13/1 do not exhibit knife-line corrosion in most nitric acid solutions, but are susceptible in mixed acid systems such as nitric acid/fluoride.

In general, welds in austenitic stainless steels are at least as corrosion resistant in nitric acid as the parent metal (see [Figure 9](#)). Their coarse-grained structure may delay the onset of grain dropping relative to the parent material, but overall penetration rates are similar. Occasionally preferential attack of weld roots may be seen.

Titanium welds can be susceptible to enhanced corrosion, both the weld metal and the heat-affected zone, in hot nitric acid solutions (see [Section 2.24.3.2](#)).

### 2.24.5.2 Cold Work

Most information on the effects of cold work on corrosion in nitric acid relates to austenitic stainless steels. The effect of cold work is intimately linked to the thermal and mechanical history of the steel and can lead to an increase or reduction in corrosion rate depending on the circumstances. Data can appear to be contradictory, and the mechanisms by which cold work affects corrosion are not fully explained, although processes such as carbon diffusion, precipitation, and martensite formation appear to be involved.<sup>43,44</sup> The relevance of the process by which cold work is achieved appears not to have been assessed and both compression by cold rolling, and tension by tensometer have been used in studying the phenomenon.

Cold work on the as-received material has generally been found to produce little effect or a marginal decrease in corrosion resistance; steels with an intrinsically lower corrosion resistance (including high Si stainless steels) and greater susceptibility to sensitization tending to fall into the latter category.<sup>43,45–47</sup> [Figure 10](#) illustrates this.

The order of cold working and thermal treatments seems to be important. Austenitic stainless steels, either sensitized<sup>46</sup> or partly sensitized as a result of cooling after prolonged solution treatment,<sup>44,48</sup> have been found to exhibit improved corrosion resistance when subsequently cold worked, although at very high levels of cold work the corrosion resistance can begin to decrease again due to martensite formation.<sup>44</sup>

**Figure 10** Effect of cold work and subsequent thermal treatment on the corrosion resistance of austenitic stainless steels in boiling 65% nitric acid. Quayle, B. E. BNFL unpublished work.

Conversely, if austenitic stainless steels are first cold worked and then sensitized, those steels having a susceptibility to sensitization show decreased corrosion resistance with increasing levels of cold work (see [Figure 10](#)), although the effect can reach a peak at relatively low deformation for some stainless steels.<sup>43</sup>

In practice, cold work is only likely to be problematical, at least for austenitic stainless steels, if they are in fact subsequently sensitized, for instance, by welding or by operation for prolonged periods at temperatures exceeding  $\sim 300^\circ\text{C}$ .<sup>43</sup>

### 2.24.5.3 NO<sub>x</sub> Gases

NO<sub>x</sub> gases dissolve in aqueous nitric acid producing nitrous acid. The resulting concentration of nitrous acid depends on temperature and it has been shown that steady state is established relatively quickly owing to solution saturation.<sup>49</sup> In the absence of other dissolved species, the redox potential of a given aqueous nitric acid solution is determined by its nitrous acid content and is amenable to calculation over a wide temperature range for a wide range of nitric acid concentrations.<sup>50</sup> Increasing nitrous acid concentration leads to an essentially perfect Nernstian decrease in solution redox potential. Nitrous acid is thus more reducing in nature than nitric acid. Metals such as zirconium exhibit the same behavior as platinum, the corrosion potential decreasing upon NO<sub>x</sub> addition. However, because nitrous acid catalyses nitrate reduction (see [Section 2.24.2.2.2](#)), the effect on stainless steels is a significant rise in the metal's corrosion potential (see [Figure 11](#)). These opposing effects on solution redox potential and stainless steel corrosion potential are explained in [Figure 12](#).

**Figure 11** Effect of  $\text{NO}_x$  purging on the corrosion potential of the indicated metals in 8 M nitric acid at 100 °C Takeuchi, M.; Whillock, G. O. H. BNFL unpublished work.

**Figure 12** Evans diagram accounting schematically for the observed effect of  $\text{NO}_x$  purging on corrosion processes occurring in nitric acid. Adapted from Takeuchi, M.; Whillock, G. O. H. *Br. Corros. J.* **2002**, 37, 199–205, with permission from Maney Publishing.

Because  $\text{NO}_x$  addition increases the corrosion potential of stainless steels in pure aqueous nitric acid solutions, the corrosion rate rises.<sup>49</sup> However, in the presence of more powerful oxidants, such as  $\text{Cr(VI)}$  or  $\text{Ce(IV)}$ ,  $\text{NO}_x$  purging significantly lowers the corrosion rate of stainless steel by reducing these strong accelerators to innocuous valency states. A similar effect was observed by Truman,<sup>51</sup> indicating the importance of considering the effect of  $\text{NO}_x$  gases in experimental design (see [Section 2.24.6](#)). In addition, the operating pressure and state of solution boiling could be of significance in some circumstances (see [Section 2.24.5.7](#)); lowering the partial pressure of  $\text{NO}_x$  gases would favor solution oxidation reactions, which would have the potential to exert a significant effect in solutions containing dissolved species such as chromium and cerium, particularly when the conditions were otherwise just insufficiently oxidizing to give significant equilibrium concentrations of  $\text{Cr(VI)}$  and  $\text{Ce(IV)}$  (see [Sections 2.24.5.4.1](#) and [2.24.5.6](#)).

## 2.24.5.4 Dissolved Oxidizing Species and Corrosion Products

### 2.24.5.4.1 Stainless steel

Many dissolved species capable of existing in more than one valency state can increase the corrosion rate of stainless steel in nitric acid; for instance in boiling 12 M nitric acid,  $\text{Cr(VI)}$ ,  $\text{Ce(IV)}$ ,  $\text{Au(III)}$ ,  $\text{V(V)}$ ,  $\text{Ru(VIII)}$ , and  $\text{I(VII)}$  are strong corrosion accelerators.<sup>52</sup> The effect of oxidizing species like these is to provide a facile cathodic reaction, essentially replacing nitrate reduction, which is capable of polarizing stainless steel to a potential where breakdown of the passivating film occurs (specifically,  $\text{Cr}_2\text{O}_3$  to  $\text{CrO}_3$  conversion). It was proposed that any species that forms a redox couple lying in the range 1.05–1.30  $V_{\text{SCE}}$  will produce the same effect, and hence would act as a strong accelerator.<sup>52</sup> This appears to provide a means of assessing the likely effect of species that cannot be tested easily (e.g., Pu, Np, Tc, etc).

However, this theory is incomplete in that it fails to predict the accelerating effect of a number of dissolved species, notably  $\text{Fe(III)}$  (see [Figure 13](#)<sup>53</sup>),  $\text{Np(VI)}$ ,  $\text{Ru(III)}$ , and  $\text{Pu(VI)}$ , the redox potentials of which are all too low to induce transpassivity, ranging between 0.53  $V_{\text{SCE}}$  ( $\text{Fe(II)/(III)}$ ) and 0.89  $V_{\text{SCE}}$  ( $\text{Np(V)/Np(VI)}$ ). The failure of Evans's approach<sup>52</sup> is due in part to oversimplification of the anodic metal dissolution reaction: commercial stainless steels do not remain passive until  $\text{Cr}_2\text{O}_3$  to  $\text{CrO}_3$  conversion

**Figure 13** Effect of dissolved iron on the corrosion rate of R-SUS 304ULC stainless steel in (i) 8 M nitric acid containing 1.53 M (Al+Fe) and (ii) 9 M nitric acid, both at 100 °C. Reproduced from Hirose, Y.; Suzuoki, A.; Sukekawa, M. In *1994 Fall Meeting of Atomic Energy Society of Japan*; Japan Atomic Energy Society: Japan, 1994; 70, with permission from Atomic Energy Society of Japan.

occurs; instead, grain boundary attack sets in at significantly lower potential (see [Figure 12](#)). Thus, corrosion accelerators can be considered to fall into two classes:

- species capable of polarizing stainless steel to very high potential, sufficient to promote  $\text{Cr}_2\text{O}_3$  to  $\text{CrO}_3$  conversion (i.e., Cr(VI), Ce(IV), Au(III), Ru(VIII) and I(VII));
- species capable of polarizing stainless steel to slightly lower potential where intergranular attack occurs (i.e., Fe(III), V(V), Ru(III), Np(VI), and Pu(VI)), but  $\text{Cr}_2\text{O}_3$  to  $\text{CrO}_3$  conversion does not (except perhaps at very high concentrations).

The mechanism whereby species belonging to the latter type act to elevate the corrosion potential of stainless steel has not been rigorously established. However, it is probably due to catalysis of nitrate reduction. This has previously been suggested to account for the action of dissolved iron<sup>54</sup> and neptunium,<sup>55</sup> but kinetic studies demonstrating this unequivocally have not been reported. The catalysis mechanism, if this is correct, is obscure, as Fe(II) should be unobtainable even transiently in hot nitric

**Figure 14** Effect of 0.01 M Ce (added as Ce(III)) on the corrosion rate of 18/13/1 stainless steel in boiling nitric acid solutions. Jones, F. BNFL unpublished work.

acid; it may be the case that the thermodynamic properties of the transitional complex have not been properly considered.

An important feature of species such as dissolved iron is that they will produce a persistent effect, because, in nitric acid solutions of sufficient strength and temperatures to pose a corrosion threat, they will be ever-present in their highest oxidation state. Conversely, deliberate additions of species such as Cr(VI) and Ce(IV) would not be capable of creating a persistent effect (provided the solution volume to metal surface area ratio was sufficient to preclude a complicating effect from released iron corrosion product) except in extremely oxidizing conditions where the oxidation of the reduced species proceeds reasonably quickly, because the reduced forms (i.e., Cr(III) and Ce(III)) are not corrosion accelerators *per se*, but can be converted to their oxidized forms by reaction with nitric acid if the conditions are sufficiently oxidizing. [Figure 14](#) illustrates this effect for dissolved cerium (added as Ce(III)), indicating that cerium accelerates corrosion in boiling nitric acid stronger than ~7 M. However, at lower temperature (100 °C), 8 M nitric acid can be tolerated without significant effect of dissolved cerium, since these conditions are just insufficiently oxidizing for the production of Ce(IV) in solution. But at still lower temperature (70 °C), significant production of Ce(IV) occurs in 10 M nitric acid, but Cr(III) does not act as an accelerator under these conditions because the oxidation of Cr(III) is more difficult than the oxidation of Ce(III) owing to

the more complicated chemical rearrangements required. These examples demonstrate the complex effect of temperature, nitric acid (i.e., nitrate) concentration, and dissolved species on solution oxidizing power, and hence the corrosive effect on stainless steels.

Although in hot, concentrated solutions, nitric acid is usually the most powerful oxidant present, it is not capable of polarizing stainless steel to as high a potential as can be achieved in the presence of species such as Fe(III), Cr(VI), etc.; this must be due to the kinetics of the various reduction reactions, as illustrated in [Figure 15](#). Redox potentials alone therefore provide no certain guide to the corrosive effect of dissolved species in nitric acid solutions. The valency state of potential corrosion accelerators is of critical importance (i.e., the equilibrium concentration of the most oxidized form) and this is governed by the balance between the solution oxidation rate and the reduction rate by reaction with stainless steel. It is therefore a prerequisite of successful corrosion testing that the valency states that would be present in an operating plant liquor are maintained during the course of testing.

#### 2.24.5.4.2 Other passive metals

Similar considerations can be applied to other metals as to stainless steels in terms of the effect of dissolved species on polarization behavior. The need for oxidants to be present for titanium to achieve passivity has already been noted ([Section 2.24.3.2](#)). Although the very passive metals such as zirconium and tantalum will be polarized by the presence of dissolved species, the absence of a low breakdown potential in nitric acid ensures that this is of little consequence for corrosion in most circumstances. Hence, these materials are generally suitable for use in oxidizing plant conditions where stainless steel would suffer an unacceptably high corrosion rate.

#### 2.24.5.5 Dissolved Reducing Species

Dissolved ions such as chloride and fluoride in sufficient quantity can lead to weakening of passivity in nitric acid. The process is dynamic, depending on the relative concentration of halide to nitrate and appears to occur more readily at lower temperatures as the passivating tendency of the nitric acid decreases.

**Figure 15** Schematic Evans diagram, showing increased corrosion rate due to Fe(III) and Cr(VI).

**Figure 16** Plot of corrosion state and average corrosion rate (mpy) determined from immersion tests for 1 week of 304 stainless steel in aerated HNO<sub>3</sub>/NaCl liquors at 22 °C. Reproduced from Kolman, D. G.; Ford, D. K.; Butt, D. P.; Nelson, T. O. *Corros. Sci.* **1997**, 39, 2067–2093, with permission from Elsevier.

The breakdown in passivity is readily indicated by a fall in the corrosion potential, which is intermittent at low concentrations (i.e., downward spikes are observed, increasing in frequency and duration as the halide concentration increases), but sustained at high concentrations leading to rapid active corrosion. Figure 16 maps out regions of active corrosion and passivity for AISI 304 stainless steel in nitric acid/chloride mixtures.<sup>56</sup> On the borderline between activity and passivity, sustained active corrosion can be induced by the application of ultrasound.<sup>57</sup> Although SCC, corrosion fatigue, and erosion/fretting corrosion appear not to have been reported for nitric acid/halide systems, susceptibility to all such chemicomechanical processes is expected.

An effect of chloride ions on corrosion in nitric acid is not reported for other passive metals such as zirconium and tantalum. However, zirconium, and, to much lesser extent, tantalum are sensitive to attack by fluoride ions in nitric acid. For zirconium, a significant effect is observed as low as 1 µg ml<sup>-1</sup> F<sup>-</sup>, as illustrated in Figure 17. For tantalum and Ta–40Nb alloy, an increase in corrosion rate is not seen for fluoride concentrations <10 µg ml<sup>-1</sup>.<sup>58</sup> The effect of fluoride ions can be reduced by the addition of ions such as Zr<sup>4+</sup> or Al<sup>3+</sup>, which form strong fluoride complexes, although in high fluoride concentrations, the effect appears to be difficult to suppress completely. The corrosion of zirconium is thus amenable to self-inhibition to some

**Figure 17** Effect of fluoride ion additions on the corrosion rate of zirconium 702 in boiling nitric acid solutions. Herbert, D. BNFL unpublished work.

extent, although this would not be expected in a frequently-washed situation such as condensing vapor regions. Table 4 illustrates the major effects observed.

#### 2.24.5.6 Radiation

An overview of the basic effects of ionizing radiation of all types on corrosion processes is given by Byalobzhetskii.<sup>59</sup> For nuclear reprocessing plant, the most important result of radiation is the formation of a large number of short-lived radical species, which react to produce stable molecular products. This is known as radiolysis. Radiolysis of the nitrate ion and water produces the following molecular products, although the reaction chains are long and complex involving a great number of intermediate species<sup>60,61</sup>:

Radiolytic reactions will be affected by the nitrate concentration, dissolved species, temperature and the radiation type. At high dose rates, appreciable levels of nitrous acid (up to ~0.5 g l<sup>-1</sup>) are formed, though the nitrous acid would be expected to become increasingly unstable at higher temperatures. Although the action of hydrogen peroxide has not been exhaustively assessed, it probably has little direct impact on

corrosion in hot nitric acid as it decomposes by reaction with nitric acid, producing nitrous acid.

Although data are sparse, the overall effect of the irradiation of nitric acid on corrosion appears to be similar to that produced by nitrous acid. Analogous to the effect of  $\text{NO}_x$  purging (Figure 11), in pure nitric acid solutions the corrosion potential of stainless steel is increased and hence the corrosion rate is increased slightly, as illustrated by Figure 18.<sup>62</sup> The effects of irradiation are more pronounced when nitric acid contains dissolved oxidizing species where reduction

**Table 4** Effect of fluoride ion concentration and various additions on the corrosion rate of zirconium 702 in boiling nitric acid solutions

Solution			Corrosion rate ( $\text{mm y}^{-1}$ )	
$\text{HNO}_3$ (M)	$\text{F}^-$ ( $\text{mg l}^{-1}$ )	Additions	Period 1	Period 2
12	0	—	0.001	0.001
	0.1	—	18.9	10.5
	0.1	$10 \text{ g l}^{-1} \text{ U}$	13.9	8.0
	0.1	$3.5 \text{ g l}^{-1} \text{ Bi}$	12.9	7.3
	0.1	$1.1 \text{ g l}^{-1} \text{ Al}$	1.6	1.4
3	1.8	—	29.6	29.6
	1.8	$1.8 \text{ g l}^{-1} \text{ Zr}$	19.1	20.1
	0.5	$2.4 \text{ g l}^{-1} \text{ Zr}$	1.7	1.4
	0.5	$4.8 \text{ g l}^{-1} \text{ Zr}$	0.002	0.001

**Figure 18** Effect of Co-60 radiation ( $40 \text{ kGy h}^{-1}$ ) on the corrosion rate of SUS 304ULC stainless steel in boiling (at atmospheric pressure) 9M nitric acid. Reproduced from Yamamoto, T.; Tsukui, S.; Okamoto, S.; Nagai, T.; Takeuchi, M.; Takeda, S.; Tanaka, Y. *J. Nucl. Mater.* **1996**, 228, 162–167, with permission from Elsevier.

of oxidizing species such as  $\text{Cr(VI)}$  and  $\text{Ce(IV)}$  can profoundly reduce corrosion rates by maintaining the corrosion potential below transpassivity.<sup>52</sup> Whether the oxidation by the acid or reduction by irradiation predominates depends on the nitric acid concentration and temperature, increase of either favoring oxidation, and radiation dose rate, increase of which favors reduction. The effect of radiation on the corrosion of stainless steels in nitric acid containing the oxidizing species  $\text{Cr(VI)}$ ,  $\text{Ce(IV)}$  and  $\text{Ru(III)}$  is demonstrated in Figure 19.<sup>63</sup> It is notable that in the case of  $\text{Ru(III)}$  the effect is less than for  $\text{Cr(VI)}$  and  $\text{Ce(IV)}$ .

By analogy with the behavior of  $\text{Ce(IV)}$  and  $\text{Cr(VI)}$ , it is expected that other species of the same type (i.e.,  $\text{Ru(VIII)}$ ,  $\text{I(VII)}$  and  $\text{Au(III)}$ )<sup>52</sup> would also be reduced by high radiation fields and thus exert negligible corrosive effect towards stainless steels. Redox potential considerations indicate that nitrous acid is incapable of reducing either  $\text{Fe(III)}$  or  $\text{V(V)}$ ; hence, no effect of radiation on their corrosive effect results.

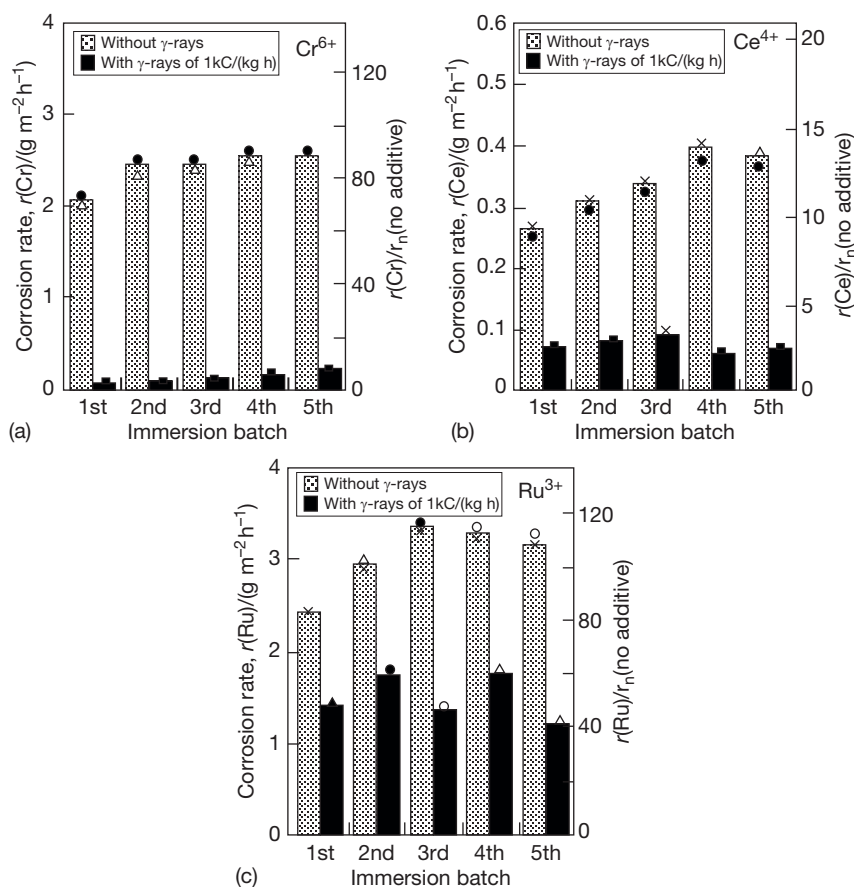

Because the corrosion resistance of metals such as zirconium and tantalum is unaffected by oxidizing species in solution (Section 2.24.5.4.2), no effect of radiation is apparent. No effect of radiation on the corrosion resistance of titanium has been reported, although a deleterious effect might be expected if reliance were placed on oxidizing ions, rather than dissolved titanium, for the maintenance of passivity.

### 2.24.5.7 Solution Boiling

The effects, if any, of boiling on corrosion processes on passive metals appear to be minimal in simple nitric acid systems. This is demonstrated by the failure of Arrhenius data to show a marked discontinuity at the boiling point (see, e.g., Figure 3). Other studies found no difference between corrosion rates measured in boiling (under reduced pressure) and nonboiling nitric acid solutions containing dissolved iron.

However, in a more complex nitric acid solution containing many dissolved species a reduction in corrosion rate is apparently found in the boiling solution. Such systems are very corrosive and there are several possible mechanisms which could occur once boiling commences including enhanced mass transport, reduction in dissolved  $\text{NO}_x$  by mechanical stripping from solution, removal of reactants and corrosion products from the reacting metal surface by agitation, local concentration effects in nucleating bubbles, limitation of corrodant access to the metal surface by gas blanketing and facilitation of interaction between dissolved species. It may be the case

**Figure 19** Effect of Co-60 radiation ( $40 \text{ kGy h}^{-1}$ ) on the corrosion rate of SUS 304ULC stainless steel in boiling 9 M nitric acid containing: (a) 0.02M Cr(VI); (b) 0.01 M Ce(IV); (c) 0.004 M Ru(III). Reproduced from Yamamoto, T.; Tsukui, S.; Okamoto, S.; Nagai, T.; Takeuchi, M.; Takeda, S.; Tanaka, Y. *J. Nucl. Sci. Technol.* **1998**, 35, 353–356, with permission from Atomic Energy Society of Japan.

that removal of iron and chromium corrosion products from the corrosion surface by agitation reduces corrosion.

In practice, individual systems may need to be tested if the possibility of a boiling effect is of interest.

#### 2.24.5.8 Heat Transfer

It would not be expected that the transfer of heat *per se* would affect corrosion processes and to date heat flux has not been demonstrated to have an effect on the corrosion process which cannot be assigned to the metal/liquor interface temperature. However, consequent processes such as changes of interface temperatures, modification of the Helmholtz layer, effects on diffusion/mass transport, solute concentration and gas blanketing under boiling could affect corrosion processes.

Data, which are limited, are principally derived from either heated disc<sup>32,64,65</sup> or heated tube rigs<sup>25,66</sup> and can be difficult to interpret. The former suffer from crevice corrosion effects on stainless steel, and the latter from difficulties in maintaining controlled and even heating.

In most simple nitric acid systems, the predominant factor determining the corrosion rate is the effective interface temperature; this will lie between that of the metal heat transfer surface and that of the liquid, but can be difficult to determine with precision. So at a constant metal surface temperature the presence of cooler acid at the metal surface under heat flux reduces the corrosion rate compared to a fully isothermal system.<sup>32,64</sup>

However, it is plausible that oxidation processes such as Cr(III) to Cr(VI) could proceed on heat transfer surfaces with a consequent increase in corrosion providing the surface is of sufficient temperature

even if the liquors are significantly cooler. When boiling occurs on the heat transfer surface, the effects may be further complicated. Although no effect of nucleate boiling on austenitic stainless steel corrosion was found at a heat flux of  $9 \text{ kW m}^{-2}$ ,<sup>32</sup> other workers indicate that boiling improves heat transfer and leads to a reduction in metal surface temperature with a consequent reduction in corrosion rate.<sup>64</sup> Conversely, other workers suggest an increased oxidizing effect on heated surfaces, generally consistent with solute rejection from nucleating voids.<sup>65</sup> It is evident that further, carefully controlled, studies are required to resolve the debate.

Industrial experience tends to support the view that corrosion processes on heated surfaces can be affected relative to isothermal surfaces, but that the effects can vary from increasing the corrosion rate where temperatures are increased at the heat transfer face to decreasing them where heating and boiling are so rapid as to create gas-blanketing effects.

### 2.24.5.9 Liquor-Line and Vapor Regions

No significant liquor-line corrosion effects have been found for stainless steel exposed to nitric acid liquors, either in operating plant or in test conditions.<sup>25</sup> Significant effects would not be expected on other passive metals.

Enhanced corrosion effects can occur in vapor-condensate phases, however. This can occur for instance where condensing films run onto heated tubes in boiler systems and are reevaporated allowing high solute concentrations to build up. In some circumstances transpassivity can be reached with consequent rapid corrosion. Instances have occurred in situations as diverse as stainless steel nitric acid transport tankers and industrial acid boilers. For stainless steels, such thin liquor film effects are considered largely to be due to corrosion product build-up, since both Fe(III) and Cr(VI) are corrosion accelerators (Section 2.24.5.4.1). Conversely, titanium is prone to corrosion in condensing systems owing to continuous removal of its corrosion products (-Section 2.24.3.2), as is aluminum (Section 2.24.3.4).

In mixed acid systems, enhanced corrosion can occur in vapor regions if preferential partitioning of the active species occurs. For stainless steels in nitric acid/chloride solutions, the formation of volatile nitrosyl chlorides may be implicated.<sup>67</sup> Preferential partitioning of fluoride to vapor occurs, hence enhanced corrosion of zirconium in vapor regions above nitric acid/fluoride liquors might be

expected; however, the absence of reports of any such effect in operating plant points to the presence of fluoride complexants that prevent or limit fluoride partitioning.

## 2.24.6 Corrosion Testing Methods

### 2.24.6.1 Ranking Tests

These are intended to indicate general trends of corrosion resistance for different materials or to show the effect of, for example, different heat treatments. They are also used to screen different batches of material procured for plant construction to ensure consistency of supply.

For stainless steels in nitric acid, the Huey test,<sup>68</sup> which is covered in both ASTM<sup>69</sup> and European standards,<sup>70</sup> is the most frequently used procedure for the assessment of intergranular or general corrosion of stainless steel. It can also form the basis of assessing general corrosion rates of other metals intended for nitric acid service. In this test, a prepared coupon is subjected to five successive 48 h test periods in boiling 65% nitric acid with the solution renewed at each period, the periodic corrosion rate being determined by weight loss. It is noted that the acid specification is more stringently controlled in the ASTM specifications with  $\text{F}^-$  limited to  $<0.1 \text{ ppm}$  as opposed to  $<3 \text{ ppm}$  in the European standard. This could be significant for some passive materials such as zirconium.

Even with such a simple test, care must be taken to ensure consistency of apparatus (e.g., the type of condenser used affects the results obtained<sup>51</sup>) and the selection of a consistent ratio of liquor volume to metal surface area, since this affects the rate of corrosion product build-up. Maintenance of a constant end, to side, to face grain ratio is essential in materials that have any susceptibility to end grain corrosion; in particular, care is needed in the selection of a consistent coupon design which avoids the exposure of excessive or varying end grain fraction (see Figure 7). Although not recommended in the test procedures, some assessment and recording of the attack on the end grain is usually worthwhile. Additional periods of testing may be required to discriminate between similar materials.

### 2.24.6.2 Prediction of In-Service Corrosion Rates

Owing to the dependence of the corrosion rate of stainless steels in nitric acid on microstructural

orientation (see [Section 2.24.4.1](#)), corrosion rates derived from periodic weighing of immersed coupons can significantly overestimate in-service corrosion rates and can also be subject to considerable variability if different coupon designs are used; the latter in particular prevents meaningful comparison of test data in a great many instances. Conversely, owing to the progressive nature of intergranular attack, short-term tests can lead to significant underestimation of in-service corrosion rates. These problems can be overcome in a number of ways:

- direct measurement of the corrosion rate by metallurgical sectioning transverse to the surface of interest (this works only for relatively short test times otherwise grain dropping removes the initial surface)<sup>30</sup>;
- short-term weight loss measurements made on specially-prepared coupons where the surface of interest has been corroded to the grain dropping stage, but all other surfaces are freshly-ground<sup>24</sup>;
- weight loss measurements made on a series of coupons specially prepared to have very different ratios of plate, side and end surfaces, all these previously having been corroded to the grain-dropping stage.<sup>30</sup>

In addition, it is possible to seal exposed end grain by overlaying it with weld metal,<sup>71</sup> but this can produce undesirable metallurgical changes and usually requires excessively large coupons unless laser techniques are employed.

All these methods are time consuming, but are necessary where a high confidence of plant life prediction is required. However, none are effective at predicting pit depths where tunneling occurs on the end grain,<sup>30</sup> so prediction of forging life, for instance, is difficult.

Great care must of course be paid to reproducing anticipated plant conditions as closely as possible owing to the many factors which affect the corrosion rate (see [Section 2.24.5](#)).

### Abbreviations

**CR** Corrosion rate (mm year<sup>-1</sup>)

### Symbols

**A** Surface area of the steel (m<sup>2</sup>)

**A/V** Surface to volume ratio (m<sup>-1</sup>)

**A<sub>(FeCO<sub>3</sub>)</sub>** Constant in the Arrhenius-type equation for  
 $k_{r(FeCO_3)}$

**A<sub>H<sub>2</sub>S</sub>** Solid state diffusion kinetic constant for H<sub>2</sub>S  
 through mackinawite film,

$$A_{H_2S} = 2.0 \times 10^{-5} \text{ mol m}^{-2} \text{ s}^{-1}$$

**$A_{H^+}$**  Solid state diffusion kinetic constant for  $H^+$  through mackinawite film,  
 $A_{H^+} = 4.0 \times 10^{-4} \text{ mol m}^{-2} \text{ s}^{-1}$

**$A_{CO_2}$**  Solid state diffusion kinetic constant for  $CO_2$  through mackinawite film,  
 $A_{CO_2} = 2.0 \times 10^{-6} \text{ mol m}^{-2} \text{ s}^{-1}$

**$b_{a(Fe)}$**  Anodic Tafel slope for Fe oxidation (V)

**$b_{c(H^+)}$**  Cathodic Tafel slope for  $H^+$  ion reduction (V)

**$b_{c(H_2CO_3)}$**  Cathodic Tafel slope for  $H_2CO_3$  reduction (V)

**$b_{c(H_2O)}$**  Cathodic Tafel slope for  $H_2O$  reduction (V)

**$B_{(FeCO_3)}$**  Constant in the Arrhenius-type equation for  $k_{r(FeCO_3)}$  ( $\text{kJ mol}^{-1}$ )

**$c_{CO_2}$**  Bulk aqueous concentration of  $CO_2$  ( $\text{kmol m}^{-3}$ )

**$c_{CO_3^{2-}}$**  Bulk aqueous concentration of  $CO_3^{2-}$  ions ( $\text{kmol m}^{-3}$ )

**$c_{Fe^{2+}}$**  Bulk aqueous concentration of  $Fe^{2+}$  ions ( $\text{kmol m}^{-3}$ )

**$c_{H^+}$**  Bulk aqueous concentration of  $H^+$  ions ( $\text{kmol m}^{-3}$ )

**$c_{s(H^+)}$**  'Near-zero' concentration of  $H^+$  underneath the mackinawite film at the steel surface, set to  $1.0 \times 10^{-7}$  ( $\text{kmol m}^{-3}$ )

**$c_{HCO_3^-}$**  Bulk aqueous concentration of  $HCO_3^-$  ions ( $\text{kmol m}^{-3}$ )

**$c_{H_2CO_3}$**  Bulk aqueous concentration of  $H_2CO_3$  ( $\text{kmol m}^{-3}$ )

**$c_{H_2S}$**  Bulk aqueous concentration of  $H_2S$  ( $\text{kmol m}^{-3}$ )

**$c_{HS^-}$**  Bulk aqueous concentration of  $HS^-$  ions ( $\text{kmol m}^{-3}$ )

**$c_i$**  Bulk aqueous concentration of a given aqueous species ( $\text{kmol m}^{-3}$ )

**$c_{i(H_2S)}$**  Aqueous concentration of  $H_2S$  at the inner sulfide film/outer sulfide layer interface ( $\text{kmol m}^{-3}$ )

**$c_{S^{2-}}$**  Bulk aqueous concentration of  $S^{2-}$  ions ( $\text{kmol m}^{-3}$ )

**$c_{s(H_2S)}$**  'Near-zero' aqueous concentration of  $H_2S$  underneath the mackinawite film at the steel surface, set to  $1.0 \times 10^{-7}$  ( $\text{kmol m}^{-3}$ )

**$c_{o(H_2S)}$**  Aqueous concentration of  $H_2S$  at the outer sulfide layer/solution interface ( $\text{kmol m}^{-3}$ )

**$c_{s(CO_2)}$**  Aqueous concentration of  $CO_2$  underneath the mackinawite film at the steel surface

**$d$**  Characteristic dimension for a given flow geometry (m)

**$d_p$**  Diameter of a pipe (m)

**$d_c$**  Diameter of a rotating cylinder (m)

**$D$**  Diffusion coefficient of a given species ( $\text{m}^2 \text{ s}^{-1}$ )

**$D_{H_2CO_3}$**  Aqueous diffusion coefficient of  $H_2CO_3$  ( $\text{m}^2 \text{ s}^{-1}$ )

**$D_{\text{ref}(H_2CO_3)}$**  Reference aqueous diffusion coefficient of  $H_2CO_3$ ,  $D_{\text{ref},H_2CO_3} = 1.3 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  at  $25^\circ \text{C}$

**$D_{H^+}$**  Aqueous diffusion coefficient for  $H^+$

**$D_{\text{ref}(H^+)}$**  Reference aqueous diffusion coefficient for  $H^+$ ,  $D_{\text{ref}(H^+)} = 2.80 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$  at  $25^\circ \text{C}$

**$D_{H_2S}$**  Aqueous diffusion coefficient for dissolved  $H_2S$

**$D_{CO_2}$**  Aqueous diffusion coefficient for dissolved  $CO_2$ ,  $D_{CO_2} = 1.96 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$

**$E$**  Potential (V)

**$E_{\text{corr}}$**  Corrosion (open circuit) potential (V)

**$E_{\text{rev}(Fe)}$**  Reversible potential of Fe oxidation,  
 $E_{\text{rev}(Fe)} = -0.488 \text{ V}$

**$E_{\text{rev}(H^+)}$**  Reversible potential for  $H^+$  ion reduction (V)

**$E_{\text{rev}(H_2CO_3)}$**  Reversible potential for  $H_2CO_3$  reduction (V)

**$E_{\text{rev}(H_2O)}$**  Reversible potential for  $H_2O$  reduction ( $\text{A m}^{-2}$ )

**$f_{H_2CO_3}$**  Flow factor for the chemical reaction boundary layer

**$F$**  Faraday's constant,  $F = 96485 \text{ C mol}^{-1}$

**$\text{Flux}_{H_2S}$**  Flux of  $H_2S$  ( $\text{kmol m}^{-2} \text{ s}^{-1}$ )

**$\text{Flux}_{H^+}$**  Flux of  $H^+$  ions ( $\text{kmol m}^{-2} \text{ s}^{-1}$ )

**$\text{Flux}_{CO_2}$**  Flux of  $CO_2$  ( $\text{mol m}^{-2} \text{ s}^{-1}$ )

**$H_{\text{sol}(CO_2)}$**  Henry's constant for dissolution of  $CO_2$  ( $\text{bar kmol m}^{-3}$ )

**$\Delta H_{Fe}$**  Activation enthalpy for Fe oxidation,  
 $\Delta H_{Fe} = 50 \text{ kJ mol}^{-1}$

**$\Delta H_{(H^+)}$**  Activation enthalpy for  $H^+$  ion reduction,  
 $\Delta H_{(H^+)} = 30 \text{ kJ mol}^{-1}$

**$\Delta H_{(H_2CO_3)}$**  Activation enthalpy for  $H_2CO_3$  reduction,  
 $\Delta H_{(H_2CO_3)} = 57.5 \text{ kJ mol}^{-1}$

**$\Delta H_{(H_2O)}$**  Activation enthalpy for  $H_2O$  reduction,  
 $\Delta H_{(H_2O)} = 30 \text{ kJ mol}^{-1}$

**$i$**  Current density ( $\text{A m}^{-2}$ )

**$i_{\text{corr}}$**  Corrosion current density ( $\text{A m}^{-2}$ )

**$i_{a(Fe)}$**  Anodic current density of iron oxidation ( $\text{A m}^{-2}$ )

**$i_{c(H^+)}$**  Cathodic current density for  $H^+$  ion reduction ( $\text{A m}^{-2}$ )

**$i_{c(H_2CO_3)}$**  Cathodic current density for  $H_2CO_3$  reduction ( $\text{A m}^{-2}$ )

**$i_{c(H_2O)}$**  Cathodic current density for  $H_2O$  reduction ( $\text{A m}^{-2}$ )

**$i_{\text{lim}(H^+)}^d$**  Mass transfer (diffusion) limiting current density for  $H^+$  ion reduction ( $\text{A m}^{-2}$ )

**$i_{\text{lim}(H_2CO_3)}^r$**  Chemical reaction limiting current density for  $H_2CO_3$  reduction ( $\text{A m}^{-2}$ )

$i_{o(\text{Fe})}$  Exchange current density of iron oxidation ( $\text{A m}^{-2}$ )

$i_{o(\text{H}^+)}$  Exchange current density for  $\text{H}^+$  ion reduction ( $\text{A m}^{-2}$ )

$i_{o(\text{H}_2\text{CO}_3)}$  Exchange current density for  $\text{H}_2\text{CO}_3$  reduction ( $\text{A m}^{-2}$ )

$i_{o(\text{H}_2\text{O})}$  Exchange current density for water reduction ( $\text{A m}^{-2}$ )

$i_{o(\text{Fe})}^{\text{ref}}$  Reference exchange current density of Fe oxidation,  $i_{o(\text{Fe})}^{\text{ref}} = 1 \text{ A m}^{-2}$

$i_{o(\text{H}^+)}^{\text{ref}}$  Reference exchange current density of  $\text{H}^+$  oxidation,  $i_{o(\text{H}^+)}^{\text{ref}} = 0.03 \text{ A m}^{-2}$  at  $T_{\text{c,ref}} = 25^\circ\text{C}$  and pH 4

$i_{o(\text{H}_2\text{CO}_3)}^{\text{ref}}$  Reference exchange current density for  $\text{H}_2\text{CO}_3$  reduction,  $i_{o(\text{H}_2\text{CO}_3)}^{\text{ref}} = 0.06 \text{ A m}^{-2}$  at  $T_{\text{c,ref}} = 25^\circ\text{C}$ , pH 5, and  $c_{\text{H}_2\text{CO}_3,\text{ref}} = 10^{-4} \text{ kmol m}^{-3}$

$i_{o(\text{H}_2\text{O})}^{\text{ref}}$  Reference exchange current density for  $\text{H}_2\text{O}$  reduction,  $i_{o(\text{H}_2\text{O})}^{\text{ref}} = 3 \times 10^{-5} \text{ A m}^{-2}$  at  $T_{\text{c,ref}} = 20^\circ\text{C}$

$i_{\alpha(\text{H}^+)}$  Charge transfer current density for  $\text{H}^+$  ion reduction ( $\text{A m}^{-2}$ )

$i_{\alpha(\text{H}_2\text{CO}_3)}$  Charge transfer current density for  $\text{H}_2\text{CO}_3$  reduction ( $\text{A m}^{-2}$ )

$I$  Ionic strength  $\text{kmol m}^{-3}$

$k_{\text{hyd}}^{\text{b}}$  Backward reaction rate of  $\text{H}_2\text{CO}_3$  dehydration reaction ( $1 \text{ s}^{-1}$ ),  $k_{\text{hyd}}^{\text{b}} = k_{\text{hyd}}^{\text{f}} / K_{\text{hyd}}$

$k_{\text{hyd}}^{\text{f}}$  Forward reaction rate for the  $\text{CO}_2$  hydration reaction ( $1 \text{ s}^{-1}$ )

$k_{\text{m}(\text{H}^+)}$  Aqueous mass transfer coefficient for  $\text{H}^+$  ( $\text{A m}^{-2}$ )

$k_{\text{m}(\text{H}_2\text{CO}_3)}$  Aqueous mass transfer coefficient for  $\text{H}_2\text{CO}_3$  ( $\text{A m}^{-2}$ )

$k_{\text{m}(\text{H}_2\text{S})}$  Aqueous mass transfer coefficient for  $\text{H}_2\text{S}$  ( $\text{A m}^{-2}$ )

$k_{\text{m}(\text{CO}_2)}$  Aqueous mass transfer coefficient for  $\text{CO}_2$  ( $\text{A m}^{-2}$ )

$k_{\text{r}(\text{FeCO}_3)}$  Kinetic constant in the ferrous carbonate precipitation rate equation ( $1 \text{ mol}^{-1} \text{ s}^{-1}$ )

$K_{\text{hyd}}$  Equilibrium hydration constant for  $\text{CO}_2$ ,  $K_{\text{hyd}} = k_{\text{hyd}}^{\text{f}} / k_{\text{hyd}}^{\text{b}} = 2.58 \times 10^{-3}$

$K_{\text{bi}}$  Equilibrium constant for dissociation of  $\text{HCO}_3^-$  ( $\text{kmol m}^{-3}$ )

$K_{\text{bs}}$  Equilibrium constant for dissociation  $\text{HS}^-$  ( $\text{kmol m}^{-3}$ )

$K_{\text{ca}}$  Equilibrium constant for dissociation of  $\text{H}_2\text{CO}_3$  ( $\text{kmol m}^{-3}$ )

$K_{\text{hs}}$  Equilibrium constant for dissociation  $\text{H}_2\text{S}$  ( $\text{kmol m}^{-3}$ )

$K_{\text{sol}(\text{H}_2\text{S})}$  Solubility constant for dissolution of  $\text{H}_2\text{S}$  ( $\text{kmol m}^{-3} \text{ bar}^{-1}$ )

$K_{\text{sol}(\text{CO}_2)}$  Solubility constant for dissolution of  $\text{CO}_2$  ( $\text{kmol m}^{-3} \text{ bar}^{-1}$ )

$K_{\text{sp}(\text{FeCO}_3)}$  Solubility product constant for ferrous carbonate ( $\text{kmol m}^{-3} \text{ bar}^{-1}$ )

$K_{\text{sp}(\text{FeS})}^{\text{mackin}}$  Solubility product constant for mackinawite ( $\text{kmol m}^{-3} \text{ bar}^{-1}$ )

$m_{\text{os}}$  Mass of the outer sulfide layer (kg)

$M_{\text{Fe}}$  Molecular mass of iron ( $\text{kg kmol}_{\text{Fe}}^{-1}$ )

$M_{\text{FeS}}$  Molecular mass of ferrous sulfide ( $\text{kg kmol}_{\text{FeS}}^{-1}$ )

$n$  Number of electrons used in reducing or oxidizing a given species ( $\text{kmol}_e \text{ kmol}^{-1}$ )

$p_{\text{CO}_2}$  Partial pressure of  $\text{CO}_2$  (bar)

$p_{\text{H}_2\text{S}}$  Partial pressure of  $\text{H}_2\text{S}$  (bar)

$R$  Electrochemical reaction rate ( $\text{kmol m}^{-2} \text{ s}^{-1}$ )

$R_{\text{FeCO}_3}$  Precipitation rate for iron carbonate ( $\text{kmol m}^{-3} \text{ s}^{-1}$ )

$R$  Universal gas constant,  $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$

$Re$  Reynolds number,  $Re = v \rho_{\text{H}_2\text{O}} d / \mu_{\text{H}_2\text{O}}$

$Sc$  Schmidt number of a given species,  $Sc = \mu_{\text{H}_2\text{O}} / (\rho_{\text{H}_2\text{O}} D)$

$Sh_p$  Sherwood number of a given species for a straight pipe flow geometry,  $Sh_p = k_m d_p / D$

$Sh_r$  Sherwood number of a given species for a rotating cylinder flow geometry,  $Sh_r = k_m d_c / D$

$SS_{(\text{FeCO}_3)}$  Supersaturation of iron carbonate

$ST$  Scaling tendency

$T_{\text{c}}$  Temperature ( $^\circ\text{C}$ )

$T_{\text{c,ref}}$  Reference temperature,  $T_{\text{c,ref}} = 25^\circ\text{C}$

$T_{\text{f}}$  Temperature ( $^\circ\text{F}$ )

$T_{\text{k}}$  Temperature (K)

$v$  Water characteristic velocity ( $\text{m s}^{-1}$ )

$z_i$  Species charge of various aqueous species

$\delta_{\text{m}(\text{H}_2\text{CO}_3)}$  Thickness of the mass transfer layer for  $\text{H}_2\text{CO}_3$  (m)

$\delta_{\text{r}(\text{H}_2\text{CO}_3)}$  Thickness of the chemical reaction layer for  $\text{H}_2\text{CO}_3$  (m)

$\delta_{\text{os}}$  Thickness of the outer sulfide layer (m),  $\delta_{\text{os}} = m_{\text{os}} / (\rho_{\text{FeS}} A)$

$\Delta t$  Time interval (s)

$\mu_{\text{H}_2\text{O}}$  Water dynamic viscosity (Pa s)

$\mu_{\text{H}_2\text{O,ref}}$  Reference water dynamic viscosity (Pa s) at a reference temperature,  $\mu_{\text{H}_2\text{O,ref}} = 1.002 \times 10^{-4} \text{ Pa s}$  at  $20^\circ\text{C}$

$\zeta_{\text{H}_2\text{CO}_3}$  Ratio of the mass transfer layer and chemical reaction thicknesses for  $\text{H}_2\text{CO}_3$

$\epsilon$  Outer sulfide layer porosity

$\psi$  Outer sulfide layer tortuosity factor  
 $\rho_{\text{H}_2\text{O}}$  Density of water ( $\text{kg m}^{-3}$ )  
 $\rho_{\text{Fe}}$  Density of iron ( $\text{kg m}^{-3}$ )  
 $\rho_{\text{FeS}}$  Density of ferrous sulfide ( $\text{kg m}^{-3}$ )

## 2.25.1 Introduction

As oil and gas emerge from the geological formation, they are always accompanied by some water and varying amounts of 'acid gases': carbon dioxide,  $\text{CO}_2$ , and hydrogen sulfide,  $\text{H}_2\text{S}$ . This is a corrosive combination, which affects the integrity of mild steel. This has been known for over 100 years; aqueous  $\text{CO}_2$  and  $\text{H}_2\text{S}$  corrosion of mild steel still represents a significant problem for the oil and gas industry.<sup>1</sup> Although corrosion resistant alloys that are able to withstand this type of corrosion exist, mild steel is often the most cost effective construction material used in this industry for these applications. All the pipelines, many wells, and much of the processing equipment in the oil and gas industry are built out of mild steel. The cost of equipment failure due to internal  $\text{CO}_2/\text{H}_2\text{S}$  corrosion is enormous, both in terms of direct costs such as repair costs and lost production, as well as in indirect costs such as environmental cost, impact on the downstream industries, etc.

The following section summarizes the degree of understanding of the so-called 'sweet'  $\text{CO}_2$  corrosion and the so-called 'sour' or  $\text{H}_2\text{S}$  corrosion of mild steel exposed to aqueous environments. It also casts the knowledge in the form of mathematical equations whenever possible. This should enable corrosion engineers and scientists to build entry level corrosion simulation and prediction models.

## 2.25.2 Aqueous $\text{CO}_2$ Corrosion of Mild Steel

Aqueous  $\text{CO}_2$  corrosion of carbon steel is an electrochemical process involving the anodic dissolution of iron and the cathodic evolution of hydrogen. The overall reaction is

$\text{CO}_2$  corrosion of mild steel is reasonably well understood. A number of chemical, electrochemical, and transport processes occur simultaneously. They are briefly described below.

### 2.25.2.1 Chemistry of $\text{CO}_2$ Saturated Aqueous Solutions – Equilibrium Considerations

$\text{CO}_2$  gas is soluble in water:

For ideal gases and ideal solutions in equilibrium, Henry's law can be used to calculate the aqueous concentration of dissolved  $\text{CO}_2$ ,  $c_{\text{CO}_2}$ , given that the respective concentration in the gas phase (often expressed in terms of partial pressure,  $p_{\text{CO}_2}$ ) is known:

$$H_{\text{sol}(\text{CO}_2)} = \frac{1}{K_{\text{sol}(\text{CO}_2)}} = \frac{p_{\text{CO}_2}}{c_{\text{CO}_2}} \quad [3]$$

The  $\text{CO}_2$  solubility constant,  $K_{\text{sol}(\text{CO}_2)}$ , is a function of temperature,  $T_f$ , and ionic strength,  $I$ :<sup>2</sup>

$$K_{\text{sol}(\text{CO}_2)} = \frac{14.5}{1.00258} \times 10^{-(2.27 + 5.65 \times 10^{-3} T_f - 8.06 \times 10^{-6} T_f^2 + 0.075 I)} \quad [4]$$

Ionic strength,  $I$ , can be calculated as

$$I = \frac{1}{2} \sum_i c_i z_i^2 = \frac{1}{2} (c_1 z_1^2 + c_2 z_2^2 + \dots) \quad [5]$$

The concentration of  $\text{CO}_2$  in the aqueous phase is of the same order of magnitude as the one in the gas phase. For example, at  $p_{\text{CO}_2} = 1$  bar, at  $25^\circ\text{C}$ , the gaseous  $\text{CO}_2$  concentration is  $\sim 4 \text{ mol l}^{-1}$  ( $\text{kmol}^{-1} \text{ m}^{-3}$ ) while in the water it is about  $3 \text{ mol l}^{-1}$ . Since the solubility of  $\text{CO}_2$  decreases with temperature, at  $100^\circ\text{C}$ , the respective concentrations are  $3.3 \text{ mol l}^{-1}$  in the gas and  $1.1 \text{ mol l}^{-1}$  in water.

A rather small fraction (about 1 in 500) of the dissolved  $\text{CO}_2$  molecules hydrates to make a 'weak' carbonic acid,  $\text{H}_2\text{CO}_3$ :

due to a relatively slow forward (hydration) rate. Assuming that the concentration of water remains unchanged, the equilibrium concentration  $c_{\text{H}_2\text{CO}_3}$  is determined by:

$$K_{\text{hyd}} = \frac{c_{\text{H}_2\text{CO}_3}}{c_{\text{CO}_2}} \quad [7]$$

The equilibrium hydration/dehydration constant,  $K_{\text{hyd}} = 2.58 \times 10^{-3}$ , does not change much across the typical temperature range of interest ( $20$ – $100^\circ\text{C}$ ).<sup>3</sup>

Carbonic acid is considered to be 'weak' because it only partially dissociates in water to produce

hydronium,  $H^+$  ions and bicarbonate ions,  $HCO_3^-$ :

The  $HCO_3^-$  dissociates further to give some more  $H^+$  and carbonate ion,  $CO_3^{2-}$ :

The respective equilibrium relations can be written as

$$K_{ca} = \frac{c_{H^+} c_{HCO_3^-}}{c_{H_2CO_3}} \quad [10]$$

$$K_{bi} = \frac{c_{H^+} c_{CO_3^{2-}}}{c_{HCO_3^-}} \quad [11]$$

The equilibrium constants can be calculated as functions of temperature  $T_f$ , and ionic strength,  $I$  as<sup>2</sup>

$$K_{ca} = 387.6 \times 10^{-6} \frac{-(6.41 - 1.594 \times 10^{-3} T_f + 8.52 \times 10^{-6} T_f^2 - 3.07 \times 10^{-5} p \times 14.7 - 0.4772 I^{0.5} + 0.118 I)}{T_f} \quad [12]$$

$$K_{bi} = 10^{-\frac{(10.61 - 4.97 \times 10^{-3} T_f + 1.331 \times 10^{-5} T_f^2 - 2.624 \times 10^{-5} p \times 14.7 - 1.166 I^{0.5} + 0.3466 I)}{T_f}} \quad [13]$$

One can use the equations above to calculate the pH for a pure aqueous  $CO_2$  saturated system. Assuming that the concentration of  $CO_2$  (or partial pressure,  $p_{CO_2}$ ) in the gas phase is known, one can calculate the concentration of aqueous/dissolved  $CO_2$   $c_{CO_2}$ , via eqn [3]. Then the concentration  $c_{H_2CO_3}$  can be determined via eqn [7]. However, in the remaining

two eqns [12] and [13], there are three unknowns:  $c_{H^+}$ ,  $c_{HCO_3^-}$ , and  $c_{CO_3^{2-}}$ , and therefore one more equation is needed to close the system: a constraint that describes charge conservation, that is, electroneutrality of the solution. Clearly, chemical reactions [8] and [9], which involve ions, always remain balanced with respect to charge and therefore one can write

$$c_{H^+} = c_{HCO_3^-} + 2c_{CO_3^{2-}} \quad [14]$$

Now, the system of equations is closed and concentrations of all the aqueous species can be determined, including the  $c_{H^+}$  and the corresponding pH. The pH of pure water as a function of  $p_{CO_2}$  at room temperature is shown in Figure 1.

If there are other ions in the aqueous solution, such as for example  $Fe^{2+}$  produced by corrosion of steel, then eqn [14] is extended to read

$$2c_{Fe^{2+}} + c_{H^+} = c_{HCO_3^-} + 2c_{CO_3^{2-}} \quad [15]$$

By inspecting the equations above, one can see that, as iron dissolution causes an increase in  $c_{Fe^{2+}}$ , it is accompanied by a decrease of  $c_{H^+}$  due to the cathodic reaction and a corresponding increase in pH. Other cations and anions as well as other chemical reactions can be introduced into the mix in a similar way. An example of a  $CO_2$  aqueous species distribution as a function of pH for an open system is given in Figure 2.

It is worth noting that this simple water chemistry calculation procedure is valid only for the case when the concentration of gaseous  $CO_2$ , i.e., the partial

**Figure 1** Calculated pH of a pure aqueous solution saturated with  $CO_2$  as a function of partial pressure of  $CO_2$ ;  $T = 25^\circ C$ , 1 wt% NaCl.

**Figure 2** Calculated carbonic species concentrations as a function of pH for a  $\text{CO}_2$  saturated aqueous solution;  $p_{\text{CO}_2}=1$  bar,  $25^\circ\text{C}$ , 1 wt% NaCl.

pressure,  $p_{\text{CO}_2}$  is known, constant, and independent from what is happening in the aqueous phase. This is often referred to as an *open* system. It is relevant to field situations where there is an overwhelming amount of  $\text{CO}_2$  in the gas phase (such as seen in wet gas lines, multiphase pipelines, gas/liquid separators, etc.). In the lab setting, this condition is easily achieved by continuous purge of a vessel with gaseous  $\text{CO}_2$ .

In contrast, there are many systems where there is a limited amount of  $\text{CO}_2$  in the gas phase compared to the amount in the liquid phase, such as in oil well tubing, oil transportation lines, liquid/liquid separators, etc. In the lab, aqueous systems with a limited gas phase are frequently found in high-pressure autoclaves and flow loops. Consequently they are often referred to as *closed* systems, and in principle can have varying gas/liquid volume ratios. An *open* system can be seen as a *closed* system with an infinitely large gas/liquid volume ratio. In *closed* systems, the concentration of gaseous  $\text{CO}_2$ , that is, the partial pressure,  $p_{\text{CO}_2}$ , is not known explicitly and typically depends on the aqueous chemistry. In mathematical terms, this means that there is one more unknown:  $p_{\text{CO}_2}$ , and therefore one needs one more equation to be able to solve for species concentrations. The extra equation comes from the additional constraint: in a *closed* system, the total amount of carbonic species remains constant; they are just redistributed between the gas and aqueous

phases as conditions change. When one accounts for this, an extra equation is obtained:

$$n_{\text{CO}_2(\text{g})} + n_{\text{CO}_2(\text{aq})} + n_{\text{H}_2\text{CO}_3(\text{aq})} + n_{\text{HCO}_3^-(\text{aq})} + n_{\text{CO}_3^{2-}(\text{aq})} = \text{Const.} \quad [16]$$

where  $n$  denotes the number of moles of a particular species in a gaseous or aqueous phase of a *closed* system.

The dissociation steps [8] and [9] are very fast compared to all other processes occurring simultaneously in corrosion of mild steel, thus preserving chemical equilibrium. However, the  $\text{CO}_2$  dissolution reaction [2] and the hydration reaction [6] are much slower. When such chemical reactions proceed slowly, other faster processes (such as electrochemical reactions or diffusion) can lead to local nonequilibrium in the solution.

Either way, the occurrence of chemical reactions can significantly alter the rate of electrochemical processes at the surface and the rate of corrosion. This is particularly true when, due to high local concentrations of species, the solubility limit of salts is exceeded and precipitation of a surface layer occurs. In a precipitation process, heterogeneous nucleation occurs first on the surface of the metal or within the pores of an existing layer since homogenous nucleation in the bulk requires a much higher concentration of species. Nucleation is followed by crystalline layer growth.

Under certain conditions, surface layers can become very protective and reduce the rate of corrosion.

In  $\text{CO}_2$  corrosion, when the concentrations of  $\text{Fe}^{2+}$  and  $\text{CO}_3^{2-}$  ions exceed the solubility limit, they form solid ferrous carbonate according to

where the solubility product constant for ferrous carbonate  $K_{\text{sp}}(\text{FeCO}_3)$  is<sup>4</sup>

$$K_{\text{sp}}(\text{FeCO}_3) = 10^{-\frac{(59.3498 - 0.041377 T_k - (2.1963/T_k))}{+24.5724 \log T_k + 2.5187^{0.5} - 0.6571}} \quad [18]$$

Actually ferrous and carbonate ions are frequently found in the aqueous solution at concentrations much higher than predicted by the equilibrium  $K_{\text{sp}}(\text{FeCO}_3)$ . This is termed *supersaturation* and is a necessary condition before any substantial precipitation can occur. The ferrous carbonate supersaturation,  $\text{SS}_{(\text{FeCO}_3)}$ , is defined as:

$$\text{SS}_{(\text{FeCO}_3)} = \frac{c_{\text{Fe}^{2+}} c_{\text{CO}_3^{2-}}}{K_{\text{sp}}(\text{FeCO}_3)} \quad [19]$$

The precipitation process can be seen as the process of the solution returning to equilibrium and is driven by the magnitude of supersaturation. The rate of the precipitation ( $\mathfrak{R}_{\text{FeCO}_3}$ ) is therefore often expressed as

$$\mathfrak{R}_{\text{FeCO}_3} = k_{\text{r}}(\text{FeCO}_3) \frac{A}{V} K_{\text{sp}}(\text{FeCO}_3) (\text{SS}_{(\text{FeCO}_3)} - 1) \quad [20]$$

where  $k_{\text{r}}(\text{FeCO}_3)$  is a kinetic constant, which can be derived from the experimental results as a function of temperature, using an Arrhenius' type equation<sup>5</sup>

$$k_{\text{r}}(\text{FeCO}_3) = \exp\left(A_{(\text{FeCO}_3)} - \frac{B_{(\text{FeCO}_3)}}{RT_k}\right) \quad [21]$$

where  $A_{(\text{FeCO}_3)} = 28.2$  and  $B_{(\text{FeCO}_3)} = 64851 \text{ J mol}^{-1}$ .

SEM images of a crystalline ferrous carbonate layer formed on a mild steel substrate are shown in **Figure 3**. The ferrous carbonate layer can slow down the corrosion process by presenting a diffusion barrier for the species involved in the corrosion process, thereby changing the conditions at the steel surface. The effective protectiveness of a solid ferrous carbonate layer depends on its porosity, which hangs in the balance of the precipitation rate and the underlying corrosion rate. For high precipitation rates, and low corrosion rates, a dense and protective ferrous carbonate layer is obtained, and conversely, low precipitation rates and high corrosion rates lead to the formation of porous unprotective ferrous carbonate layers. A non-dimensional parameter termed 'scaling

**Figure 3** SEM images showing a cross-section and a top view of a ferrous carbonate layer formed on mild steel;  $80^\circ\text{C}$ ,  $\text{pH } 6.6$ ,  $p_{\text{CO}_2} = 0.5 \text{ bar}$ , stagnant conditions.

tendency' (ST) can be used to quantify the relative rates of precipitation ( $\mathfrak{R}_{\text{FeCO}_3}$ ) and corrosion (CR) expressed in the same volumetric units:

$$\text{ST} = \frac{\mathfrak{R}_{\text{FeCO}_3}}{\text{CR}} \quad [22]$$

For  $\text{ST} \ll 1$ , porous and unprotective films are likely to form. Conversely, for  $\text{ST} \geq 1$ , conditions become favorable for the formation of dense, protective ferrous carbonate films. However, the use of scaling tendency is not as straightforward as it appears, as it requires simultaneous calculation of  $\mathfrak{R}_{\text{FeCO}_3}$  and corrosion CR.

In some cases, other salts can be detected in the surface layers that form on mild steel. In high temperature  $\text{CO}_2$  corrosion magnetite ( $\text{Fe}_3\text{O}_4$ ) has been detected. In the presence of oxygen, a ferric oxide hematite ( $\text{Fe}_2\text{O}_3$ ), which is very insoluble but offers little protection from corrosion forms. Oilfield scales also include calcium carbonate, calcium sulfate,

barium sulfate, strontium sulfate, etc. The presence of calcium carbonate, in particular, can have a beneficial effect upon corrosion and upon the stability of the  $\text{FeCO}_3$  scale. Finally, in the presence of  $\text{H}_2\text{S}$ , various types of sulfides form as discussed in a separate section below.

### 2.25.2.2 Electrochemistry of Mild Steel Corrosion in $\text{CO}_2$ Saturated Aqueous Solutions

The electrochemical dissolution of iron in a water solution:

is the dominant anodic reaction in  $\text{CO}_2$  corrosion. The reaction is pH dependent in acidic solutions with a reaction order with respect to  $\text{OH}^-$  between 1 and 2, decreasing toward 1 and 0 at  $\text{pH} > 4$ , which is the typical range for  $\text{CO}_2$  corrosion. Measured Tafel slopes are typically 30–80 mV. This subject, which is still somewhat controversial with respect to the mechanism, has been reviewed for acidic corrosion<sup>6,7</sup> and  $\text{CO}_2$  solutions.<sup>8</sup>

The presence of  $\text{CO}_2$  increases the rate of corrosion of mild steel in aqueous solutions primarily by increasing the rate of the hydrogen evolution reaction. It is well known that in *strong* acids, which are fully dissociated, the rate of hydrogen evolution occurs according to

and is, for the case of mild steel corrosion, limited by the rate at which  $\text{H}^+$  ions are transported from the bulk solution to the steel surface (mass transfer limitation). In  $\text{CO}_2$  solutions, where typically  $\text{pH} > 4$ , this limiting flux would be small, and therefore it is the presence of  $\text{H}_2\text{CO}_3$  which enables hydrogen evolution at a much higher rate. Thus, for  $\text{pH} > 4$ , the presence of  $\text{CO}_2$  leads to a much higher corrosion rate than would be found in a solution of a *strong* acid at the same pH.

This can be readily explained by considering that the homogenous dissociation of  $\text{H}_2\text{CO}_3$ , as given by reaction [8], serves as an additional source of  $\text{H}^+$  ions, which are subsequently adsorbed at the steel surface and reduced according to reaction [24].<sup>1</sup> A different pathway is also possible, where the  $\text{H}_2\text{CO}_3$  first adsorbs at the steel surface followed by heterogeneous dissociation and reduction of the  $\text{H}^+$  ion. This is

often referred to as ‘direct’ reduction of carbonic acid<sup>9–11</sup> and is written as

Clearly, the addition of the reactions [8] and [24] gives the reaction [25] proving that the overall reaction is the same and the distinction is only in the pathway, that is, in the sequence of reactions. The rate of reaction [25] is limited primarily by the slow hydration step [6]<sup>11,12</sup> and in some cases by the slow  $\text{CO}_2$  dissolution reaction [2].

It can be conceived that in  $\text{CO}_2$  solutions at  $\text{pH} > 5$  the direct reduction of the bicarbonate ion becomes important<sup>13</sup>:

which seems plausible, as the concentration of  $\text{HCO}_3^-$  increases with pH and can exceed that of  $\text{H}_2\text{CO}_3$  as seen in Figure 2. However, it is difficult to distinguish experimentally the effect of this particular reaction pathway for hydrogen evolution from the two previously discussed (eqns [8] and [25]). In addition, evidence exists that suggests that the rate of this reaction is comparatively low and can be neglected. For example, as the pH increases, the amount of  $\text{HCO}_3^-$  increases as well (see Figure 2), suggesting that the corrosion rate should follow the same trend, if one is to believe that the direct reduction of the bicarbonate ion [26] is a significant cathodic reaction. Experimental evidence does not support this scenario and shows the opposite trend: the corrosion rate actually decreases with an increasing pH, even if no protective ferrous carbonate layer forms.

Hydrogen evolution by direct reduction of water:

is always possible, but is comparatively very slow and is important only at  $p_{\text{CO}_2} \ll 0.1$  bar and  $\text{pH} > 6$ .<sup>14,15</sup> Therefore, this reaction is rarely a factor in practical  $\text{CO}_2$  corrosion situations.

The various electrochemical processes described above can be quantified using the well established electrochemical theory. The rate of the electrochemical reactions,  $\mathcal{R}$  in  $\text{kmol m}^{-2} \text{s}^{-1}$ , can be readily expressed in terms of current density,  $i$  in  $\text{A m}^{-2}$ , since the two are directly related: for example, during hydrogen evolution [24] for every kmol of  $\text{H}^+$  1 kmol of electrons is used ( $n = 1 \text{ kmol}_e \text{ kmol}^{-1}$ ), while for every kmol of iron dissolved [23] two

kmols of electrons are used ( $n = 2 \text{ kmol}_e \text{ kmol}^{-1}$ ). Therefore, one can write

$$i = nF\mathfrak{R} \quad [28]$$

### 2.25.2.2.1 Oxidation of iron

In the corrosion of mild steel, the oxidation (dissolution) of iron [23] is the dominant anodic reaction. The anodic dissolution of iron at the corrosion potential (and up to 200 mV above) is under charge transfer control. Thus, pure Tafel behavior can be assumed close to the corrosion potential:

$$i_{\text{a(Fe)}} = i_{\text{o(Fe)}} 10^{(E_{\text{corr}} - E_{\text{rev(Fe)}})/b_{\text{a(Fe)}}} \quad [29]$$

The exchange current density of iron oxidation is a function of temperature:

$$i_{\text{o(Fe)}} = i_{\text{o(Fe)}}^{\text{ref}} \exp\left(\frac{-\Delta H_{\text{Fe}}}{R} \left(\frac{1}{T_{\text{c}} + 273.15} - \frac{1}{T_{\text{c,ref}} + 273.15}\right)\right) \quad [30]$$

The Tafel slope of this reaction is given by

$$b_{\text{a(Fe)}} = \frac{2.303R(T_{\text{c}} + 273.15)}{1.5F} \quad [31]$$

### 2.25.2.2.2 Reduction of hydronium ion

In general, the  $\text{H}^+$  ion reduction reaction [24] can be either under charge transfer or mass transfer (diffusion) control, therefore, one can write:

$$\frac{1}{i_{\text{c(H}^+)}} = \frac{1}{i_{\alpha(\text{H}^+)}} + \frac{1}{i_{\text{lim(H}^+)}}^{\text{d}} \quad [32]$$

The charge transfer current density can be calculated by

$$i_{\alpha(\text{H}^+)} = i_{\text{o(H}^+)}} \times 10^{(-E_{\text{corr}} - E_{\text{rev(H}^+)})/b_{\text{c(H}^+)}} \quad [33]$$

The exchange current density  $i_{\text{o(H}^+)}}$  is a function of pH and temperature. The pH dependence is

$$\frac{\partial \log i_{\text{o(H}^+)}}{\partial \text{pH}} = -0.5 \quad [34]$$

The temperature dependence of the exchange current density can be calculated via an Arrhenius-type relation:

$$\frac{i_{\text{o(H}^+)}}{i_{\text{o(H}^+)}}^{\text{ref}} = \exp\left(-\frac{\Delta H_{\text{(H}^+)}}{R} \left(\frac{1}{T_{\text{c}} + 273.15} - \frac{1}{T_{\text{c,ref}} + 273.15}\right)\right) \quad [35]$$

The reversible potential for  $\text{H}^+$  reduction  $E_{\text{rev(H}^+)}$  is a function of temperature and pH:

$$E_{\text{rev(H}^+)}} = -\frac{2.303R(T_{\text{c}} + 273.15)}{F} \text{pH} \quad [36]$$

The cathodic Tafel slope  $b_{\text{c(H}^+)}$  is calculated as

$$b_{\text{c(H}^+)}} = \frac{2.303R(T_{\text{c}} + 273.15)}{0.5F} \quad [37]$$

The limiting mass transfer current density  $i_{\text{lim(H}^+)}}^{\text{d}}$  is related to the rate of transport of  $\text{H}^+$  ions from the bulk of the solution through the boundary layer to the steel surface:

$$i_{\text{lim(H}^+)}}^{\text{d}} = k_{\text{m(H}^+)}} F c_{\text{H}^+} \quad [38]$$

where the mass transfer coefficient,  $k_{\text{m(H}^+)}}$  can be calculated from a correlation of the Sherwood, Reynolds, and Schmidt numbers as explained in the following section.

### 2.25.2.2.3 Reduction of carbonic acid

The carbonic acid reduction reaction [25] can be under charge transfer control or limited by the slow chemical reaction–hydration step [6], preceding it.<sup>11,12</sup> The rate of this reaction in terms of current density is

$$\frac{1}{i_{\text{c(H}_2\text{CO}_3)}} = \frac{1}{i_{\alpha(\text{H}_2\text{CO}_3)}} + \frac{1}{i_{\text{lim(H}_2\text{CO}_3)}}^{\text{r}} \quad [39]$$

The charge transfer current density  $i_{\alpha(\text{H}_2\text{CO}_3)}$  is calculated as

$$i_{\alpha(\text{H}_2\text{CO}_3)} = i_{\text{o(H}_2\text{CO}_3)}} \times 10^{(-E_{\text{corr}} - E_{\text{rev(H}_2\text{CO}_3)}})/b_{\text{c(H}_2\text{CO}_3)}} \quad [40]$$

The exchange current density  $i_{\text{o(H}_2\text{CO}_3)}}$  depends on pH,  $\text{H}_2\text{CO}_3$  concentration, and temperature:

$$\frac{\partial \log i_{\text{o(H}_2\text{CO}_3)}}{\partial \text{pH}} = 0.5 \quad [41]$$

$$\frac{\partial \log i_{\text{o(H}_2\text{CO}_3)}}{\partial c_{\text{H}_2\text{CO}_3}} = 1 \quad [42]$$

$$\frac{i_{\text{o(H}_2\text{CO}_3)}}{i_{\text{o(H}_2\text{CO}_3)}}^{\text{ref}} = \exp\left(-\frac{\Delta H_{\text{(H}_2\text{CO}_3)}}{R} \left(\frac{1}{T_{\text{c}} + 273.15} - \frac{1}{T_{\text{c,ref}} + 273.15}\right)\right) \quad [43]$$

The cathodic Tafel slope  $b_{\text{c(H}_2\text{CO}_3)}}$  is

$$b_{\text{c(H}_2\text{CO}_3)}} = \frac{2.303R(T_{\text{c}} + 273.15)}{0.5F} \quad [44]$$

Since the reductions of  $\text{H}_2\text{CO}_3$  and  $\text{H}^+$  are equivalent

thermodynamically, the reversible potential for  $\text{H}_2\text{CO}_3$  reduction  $E_{\text{rev}(\text{H}_2\text{CO}_3)}$  is calculated as

$$E_{\text{rev}(\text{H}_2\text{CO}_3)} = -\frac{2.303R(T_c + 273.15)}{F} \text{pH} \quad [45]$$

The chemical reaction limiting current density  $i_{\text{lim}(\text{H}_2\text{CO}_3)}^r$  can be calculated from<sup>16</sup>:

$$i_{\text{lim}(\text{H}_2\text{CO}_3)}^r = F \dot{c}_{\text{CO}_2} f_{\text{H}_2\text{CO}_3} \sqrt{D_{\text{H}_2\text{CO}_3} K_{\text{hyd}} k_{\text{hyd}}^f} \quad [46]$$

The diffusion coefficient for carbonic acid  $D_{\text{H}_2\text{CO}_3}$  as a function of temperature can be calculated using Einstein's relation:

$$D = D_{\text{ref}} \left( \frac{T_c + 273.15}{T_{c,\text{ref}} + 273.15} \right) \left( \frac{\mu_{\text{H}_2\text{O},\text{ref}}}{\mu_{\text{H}_2\text{O}}} \right) \quad [47]$$

where  $T$  is temperature and  $\mu$  is dynamic viscosity. The forward reaction rate for the  $\text{CO}_2$  hydration reaction  $k_{\text{hyd}}^f$  is calculated as

$$k_{\text{hyd}}^f = 10^{169.2 - 53.0 \log(T_c + 273.15) - (11715/(T_c + 273.15))} \quad [48]$$

The flow factor  $f_{\text{H}_2\text{CO}_3}$  is

$$f_{\text{H}_2\text{CO}_3} = \coth \zeta_{\text{H}_2\text{CO}_3} \quad [49]$$

where

$$\zeta_{\text{H}_2\text{CO}_3} = \frac{\delta_{\text{m}(\text{H}_2\text{CO}_3)}}{\delta_{\text{r}(\text{H}_2\text{CO}_3)}} \quad [50]$$

and

$$\delta_{\text{m}(\text{H}_2\text{CO}_3)} = \frac{D_{\text{H}_2\text{CO}_3}}{k_{\text{m}(\text{H}_2\text{CO}_3)}} \quad [51]$$

$$\delta_{\text{r}(\text{H}_2\text{CO}_3)} = \sqrt{\frac{D_{\text{H}_2\text{CO}_3}}{k_{\text{hyd}}^b}} \quad [52]$$

The carbonic acid mass transfer coefficient  $k_{\text{m}(\text{H}_2\text{CO}_3)}$  is discussed in [Section 2.25.2.3](#).

#### 2.25.2.2.4 Reduction of water

Unless water is mixed with methanol or glycol to prevent hydrate formation or somehow diluted otherwise, it can be assumed that water molecules are present in virtually unlimited quantities at the steel surface, and the reduction rate of  $\text{H}_2\text{O}$  is controlled by the charge-transfer process and, hence, pure Tafel behavior:

$$i_{\text{c}(\text{H}_2\text{O})} = i_{\text{o}(\text{H}_2\text{O})} 10^{-(E_{\text{corr}} - E_{\text{rev}(\text{H}_2\text{O})})/b_{\text{c}(\text{H}_2\text{O})}} \quad [53]$$

Since the reduction of  $\text{H}_2\text{O}$  and  $\text{H}^+$  are equivalent thermodynamically, they have the same reversible potential at a given pH:

$$E_{\text{rev}(\text{H}_2\text{O})} = -\frac{2.303R(T_c + 273.15)}{F} \text{pH} \quad [54]$$

The exchange current density for water reduction  $i_{\text{o}(\text{H}_2\text{O})}$  depends on temperature:

$$\frac{i_{\text{o}(\text{H}_2\text{O})}}{i_{\text{o}(\text{H}_2\text{O})}^{\text{ref}}} = \exp \left( -\frac{\Delta H_{(\text{H}_2\text{O})}}{R} \left( \frac{1}{T_c + 273.15} - \frac{1}{T_{c,\text{ref}} + 273.15} \right) \right) \quad [55]$$

The Tafel slope for  $\text{H}_2\text{O}$  reduction was found to be the same as that for  $\text{H}^+$  reduction:

$$b_{\text{c}(\text{H}_2\text{O})} = \frac{2.303R(T_c + 273.15)}{0.5F} \quad [56]$$

#### 2.25.2.3 Transport Processes in $\text{CO}_2$ Corrosion of Mild Steel

From the description of the electrochemical processes above, it is clear that certain species in the solution are 'produced' at the metal surface (e.g.,  $\text{Fe}^{2+}$ ) while others are depleted (e.g.,  $\text{H}^+$ ). The established concentration gradients lead to molecular diffusion of the species toward and away from the surface. In cases when the diffusion processes are much faster than the electrochemical processes, the concentration change at the metal surface is small. In contrast, when the diffusion is unable to 'keep up' with the rate of the electrochemical reactions, the concentration of species at the metal surface can become very different from that in the bulk solution. The rate of the electrochemical processes depends on the concentration of the reactants at the surface. Therefore, there exists a two-way coupling between the electrochemical processes at the metal surface (corrosion) and processes in the adjacent solution layer (i.e., diffusion in the boundary layer). The same is true for chemical reactions, which interact with both the transport and electrochemical processes in a complex way.

In most practical systems, the water solution moves with respect to the metal surface. Therefore, the effect of convection on transport processes cannot

be ignored. Turbulent eddies can penetrate deep into the hydrodynamic boundary layer and significantly alter the rate of species transport to and from the surface. Very close to the surface no turbulence can exist and the species are transported solely by diffusion. The effect of turbulent flow is captured most easily by using the concept of mass transfer coefficient, described below.

In turbulent flow of dilute ideal solutions, a mass transfer coefficient  $k_m$  for a given species ( $H^+$  ions,  $H_2CO_3$  etc.) can be calculated from a correlation, such as the straight pipe correlation of Berger and Hau<sup>25</sup>:

$$Sb_p = 0.0165 Re^{0.86} Sc^{0.33} \quad [57]$$

or the rotating cylinder correlation of Eisenberg *et al.*<sup>26</sup>:

$$Sb_r = 0.0791 Re^{0.7} Sc^{0.356} \quad [58]$$

or any other similar correlation for the flow geometry at hand. It should be noted that most of the mass transfer correlations found in the literature (including the two listed above) are suited only for single-phase flow. Therefore, extension of this approach to multiphase flow situations needs to be done with careful consideration.

Overall,  $CO_2$  corrosion of mild steel is not very sensitive to flow, at least not so when compared to mild steel corrosion in strong acids. This is due to the fact that the main corrosive species in  $CO_2$  corrosion is  $H_2CO_3$  which can easily be depleted due to a slow chemical step which precedes it: the hydration reaction [6]. Therefore, the limiting rate of  $CO_2$  corrosion is primarily affected by the rate of this chemical reaction [46], which is a function of temperature and  $CO_2$  partial pressure and not very sensitive to flow.

#### 2.25.2.4 Calculation of Mild Steel $CO_2$ Corrosion Rate

Leading to this point, the main processes underpinning  $CO_2$  corrosion were defined: the speciation of the aqueous  $CO_2$  solution using the thermodynamic approach outlined in Section 2.25.2.1, the electrochemical theory described in Section 2.25.2.2, and the transport processes as covered in Section 2.25.2.3. Using this information, the corrosion rate of mild steel can now be calculated. The unknown corrosion potential  $E_{corr}$  in [33], [40], [53], and [29] can be found from the current (charge) balance equation at the steel surface:

$$i_{c(H^+)} + i_{c(H_2CO_3)} + i_{c(H_2O)} = i_{a(Fe)} \quad [59]$$

which expresses the simple fact that at steady state all the electrons generated by the oxidation processes are consumed by the sum of the reduction processes. By substituting the expressions for the various currents given by eqns [33], [40], [53], and [29] into eqn [59] a single nonlinear equation is now obtained with  $E_{corr}$  as the only unknown, which can be easily solved. When the calculated value of  $E_{corr}$  is now returned to eqns [33], [40], [53], and [29], the rate of each individual reaction can be explicitly computed. This also includes the corrosion current density obtained from eqn [29]:

$$i_{corr} = i_{a(Fe)} \quad [60]$$

Finally, the  $CO_2$  corrosion rate is recovered by using Faraday's law:

$$CR = \frac{i_{corr} M_{Fe}}{\rho_{Fe} n F} \quad [61]$$

where  $M$  is the molecular mass and  $\rho$  is the density. If the unit amperes per square meters is used for the corrosion current density  $i_{corr}$ , then conveniently the corrosion rate for iron and steel expressed in millimeter per year takes almost the same numerical value, precisely,  $CR = 1.155 i_{corr}$ .

#### 2.25.2.5 Successes and Limitations of Modeling of Aqueous $CO_2$ Corrosion of Mild Steel

Evidence that our basic understanding of the processes underlying  $CO_2$  corrosion of mild steel is reasonably sound can be found by comparing the predictions made by the mechanistic model outlined above with experimental values. In Figure 4, below, one can see the comparison of a potentiodynamic sweep obtained in the experiments and the one predicted by the model. Many other comparisons of the predicted and measured corrosion rates are given in the following section, where the effect of key factors in  $CO_2$  corrosion of mild steel is discussed.

Despite the relative progress we have made in understanding and modeling of aqueous  $CO_2$  corrosion of mild steel, many questions persist. One is the issue of localized  $CO_2$  corrosion, which is still a topic of intense ongoing research. Effect of other factors such as steel metallurgy, organic acids, oxygen, multiphase flow, and inhibitors are challenges that need further effort. Some of those are discussed in the following sections.

**Figure 4** Potentiodynamic sweep, experimental (points) vs. model (lines); 20 °C,  $p_{\text{CO}_2} = 1$  bar, pH 4,  $2 \text{ ms}^{-1}$ .

### 2.25.2.6 Key Factors Affecting Aqueous $\text{CO}_2$ Corrosion of Mild Steel

Armed with the understanding and the ability to calculate  $\text{CO}_2$  corrosion rates, as described in the sections above, in this section, the effect of key factors which affect the rate of  $\text{CO}_2$  corrosion are discussed, and the predictions made by the model are compared to empirical results.

#### 2.25.2.6.1 Effect of pH

The pH has a significant influence on the  $\text{CO}_2$  corrosion rate. Lower pH leads to higher corrosion rates and vice versa, just like in many other acidic solutions. Typical pH in  $\text{CO}_2$  saturated condensed water is about pH 4 while in buffered brines, one frequently encounters  $5 < \text{pH} < 7$ . At pH 4 or below, direct reduction of  $\text{H}^+$  ions, reaction [24], is important, particularly at lower partial pressures of  $\text{CO}_2$ , when direct reduction of carbonic acid, reaction [25], can be ignored. In that case, the pH has a direct effect on the corrosion rate. Another important effect of pH is indirect and relates to how pH changes conditions for the formation of ferrous carbonate layers. Higher pH ( $5 < \text{pH} < 7$ ) results in a decreased solubility of ferrous carbonate and leads to an increased precipitation rate and a higher scaling tendency. The effect of various pH and

supersaturations are shown in Figure 5. At lower supersaturations obtained at the lower pH of 6, shown in Figure 5, the corrosion rate does not change much with time, even if some ferrous carbonate precipitation occurs, reflecting the fact that a relatively porous, detached and unprotective layer is formed (low scaling tendency ST). The higher pH of 6.6 results in higher supersaturation, faster precipitation, and formation of more protective ferrous carbonate, reflected by a rapid decrease of the corrosion rate with time. There are other indirect effects of pH, and by almost all accounts, higher pH leads to a reduction of the corrosion rate, making the ‘pH stabilization’ (meaning: pH increase) technique an attractive way of managing  $\text{CO}_2$  corrosion. The drawback of this technique is that it can lead to excessive scaling and can rarely be used with formation water systems.

#### 2.25.2.6.2 Effect of $\text{CO}_2$ partial pressure

In the case of scale-free  $\text{CO}_2$  corrosion, an increase of  $p_{\text{CO}_2}$  typically leads to an increase in the corrosion rate. The commonly accepted explanation is that with increasing  $p_{\text{CO}_2}$  the concentration of  $\text{H}_2\text{CO}_3$  increases and accelerates the cathodic reaction, eqn [25], and ultimately the corrosion rate. The detrimental effect of  $p_{\text{CO}_2}$  at a constant pH is illustrated in Figure 6. The model described above reasonably

**Figure 5** Effect of ferrous carbonate supersaturation  $SS_{(FeCO_3)}$  on corrosion rate obtained at a range of pH 6.0–6.6, for  $5 \text{ ppm} < c_{Fe^{2+}} < 50 \text{ ppm}$  at  $T = 80^\circ\text{C}$ , under stagnant conditions. Error bars represent minimum and maximum values obtained in repeated experiments. Data taken from Chokshi *et al.*<sup>17</sup>

**Figure 6** The effect of  $\text{CO}_2$  partial pressure,  $p_{\text{CO}_2}$  on bare steel corrosion rate, comparison of experimental results (points) and model (line);  $60^\circ\text{C}$ , pH 5,  $1 \text{ m s}^{-1}$ , 100 mm ID single-phase pipe flow.

captures well this trend up to approximately  $p_{\text{CO}_2} = 10 \text{ bar}$ . However, when other conditions are favorable for the formation of ferrous carbonate layers, increased  $p_{\text{CO}_2}$  can have a beneficial effect. At a high pH, higher  $p_{\text{CO}_2}$  leads to an increase in bicarbonate and carbonate ion concentration and a higher supersaturation which accelerates precipitation and protective layer formation. The effect of  $p_{\text{CO}_2}$  on the corrosion rate in the presence of ferrous carbonate precipitation is illustrated in Figure 7 where in stratified wet gas flow, corrosion rate is reduced both at top and bottom of the pipe with the increase partial pressure of  $\text{CO}_2$ .

#### 2.25.2.6.3 Effect of temperature

Temperature accelerates all the processes involved in corrosion: electrochemical, chemical, transport, etc. One would expect then that the corrosion rate steadily increases with temperature, and this is the case at low pH when precipitation of ferrous carbonate or other protective layers does not occur. An example is shown Figure 8. The situation changes markedly when solubility of ferrous carbonate is exceeded, typically at a higher pH. In that case, increased temperature rapidly accelerates the kinetics of precipitation and protective layer formation, decreasing the corrosion rate. The peak in the

**Figure 7** Experimental measurements of the corrosion rate at the top and bottom of the pipe in stratified gas–liquid flow showing the effect of CO<sub>2</sub> partial pressure,  $p_{\text{CO}_2}$ , on formation of ferrous carbonate layer. Test conditions: 90 °C, pH 6, 100 mm ID,  $V_{\text{sg}} = 10 \text{ m s}^{-1}$ ,  $V_{\text{sl}} = 0.1 \text{ m s}^{-1}$ . Data taken from Sun and Nešić.<sup>18</sup>

**Figure 8** The effect of temperature on CO<sub>2</sub> corrosion rate of mild steel; pH 4,  $p_{\text{CO}_2} = 1 \text{ bar}$ , 100 mm ID single phase pipe flow. Points are experimental values and the solid line is the model. The dotted line is a model simulation of the same conditions at pH 6.6 accounting for protective ferrous carbonate film formation.

corrosion rate is usually seen between 60 and 80 °C depending on water chemistry and flow conditions as shown in Figure 8 (dotted line).

#### 2.25.2.6.4 Effect of flow

There are two main ways in which flow may affect CO<sub>2</sub> corrosion, which can be distinguished based on whether or not other conditions are conducive to protective layer formation or not.

In the case of corrosion where protective layers do not form (typically at low pH as found in condensed water and in the absence of inhibitors), the main role of turbulent flow is to enhance transport of species toward and away from the metal surface. This may

lead to an increase in the corrosion rate as illustrated in Figure 9. At lower pH 4, the effect is much more pronounced as the dominant cathodic reaction is direct H<sup>+</sup> ion reduction [24], which is under mass transfer control (see eqn [38]).

When protective ferrous carbonate layers form (typically at higher pH in produced water) or when inhibitor films are present on the steel surface, the above-mentioned effect of flow becomes insignificant as the main resistance to corrosion is now in the surface layer or inhibitor film. In this case, the effect of flow is to interfere with the formation of protective surface layers or to remove them once they are in place, often leading to an increased risk of localized attack.

The two flow accelerated corrosion effects discussed above are frequently aggravated by flow disturbances such as valves, constrictions, expansions, bends, etc. where local increases of near-wall turbulence and wall-shear stress are seen. However, flow can lead to onset of localized attack only when given the ‘right’ set of circumstances as discussed in a separate heading below.

The effect of multiphase flow on CO<sub>2</sub> corrosion is complicated by the different flow patterns that exist, the most common being *stratified*, *slug*, and *annular-mist* flow. In the liquid phase, water and oil can flow separated or mixed with either phase being continuous with the other flowing as a dispersed phase. Different flow patterns lead to a variety of steel surface wetting mechanisms: stable water wetting, stable oil wetting, intermittent wetting, etc., which

**Figure 9** Predicted (line) and experimentally measured corrosion rates (points) showing the effect of velocity in the absence of ferrous carbonate layers. Test conditions: 20 °C,  $p_{\text{CO}_2} = 1$  bar, 15 mm ID single-phase pipe flow. Experimental data taken from Nešić *et al.*<sup>19</sup>

greatly affect corrosion. In annular mist flow, the liquid droplets move at high velocity and can lead to protective layer damage at points of impact such as bends, valves, tees, constrictions/expansions, and other pipe fittings. Slug flow can lead to significant short-lived fluctuations in the wall-shear stress, which can help remove a protective surface layer of ferrous carbonate or possibly affect an inhibitor film.

#### 2.25.2.6.5 Effect of corrosion inhibition

The two most common sources of corrosion inhibition need to be considered:

- inhibition by addition of corrosion inhibitors and
- inhibition by components present in the crude oil.

#### Corrosion inhibitors

Describing the effect of corrosion inhibitors is not a straightforward task due to the enormous complexity of the subject. Quantifying them and predicting their behavior are even harder. There is a plethora of approaches in the open literature, varying from the use of simple *inhibitor factors* and *inhibition efficiencies* to the application of complicated *molecular modeling* techniques to describe inhibitor interactions with the steel surface and ferrous carbonate layer. A middle-of-the-road approach is based on the assumption that corrosion protection is achieved by *surface coverage*, that is, that the inhibitor adsorbs onto the steel surface and slows down one or more electrochemical reactions by ‘blocking.’ The degree of protection is

assumed to be directly proportional to the fraction of the steel surface blocked by the inhibitor. In this type of model, one needs to establish a relationship between the surface coverage  $\theta$  and the inhibitor concentration in the solution  $c_{\text{inh}}$ . This is most commonly done by the use of adsorption isotherms.

#### Corrosion inhibition by crude oil

It has been known for a while that  $\text{CO}_2$  corrosion rates seen in the field in the presence of crude oil are much lower than those obtained in laboratory conditions where crude oil was not used or synthetic crude oil was used. One can identify two main effects of crude oil on the  $\text{CO}_2$  corrosion rate.

The first is a *wettability* effect and relates to a hydrodynamic condition where crude oil entrains the water and prevents it from wetting the steel surface (continuously or intermittently).

The second effect is *corrosion inhibition* by components of the crude oil that reach the steel surface either by direct contact or by first partitioning into the water phase. Various surface active organic compounds found in crude oil (typically oxygen, sulfur and nitrogen containing molecules) have been identified to directly inhibit corrosion of mild steel in  $\text{CO}_2$  solutions.

#### 2.25.2.6.6 Effect of organic acids

The low molecular weight organic acids are primarily soluble in water and can lead to corrosion of mild steel. Higher molecular weight organic acids are not water soluble, but are typically soluble in the oil phase and pose a corrosion threat at higher temperatures in the refineries. Acetic acid  $\text{CH}_3\text{COOH}$  (denoted as HAc in the text below) is the most prevalent low molecular weight organic acid found in brines. Other acids typically found in the brine are propionic, formic, etc.; however, their behavior and corrosiveness is very similar to that of HAc and therefore HAc can be used as a 'surrogate' for all the organic acids found in the brine. HAc is a weak acid; however, it is stronger than  $\text{H}_2\text{CO}_3$  ( $pK_a$  4.76 vs. 6.35 at 25 °C), and it is the main source of  $\text{H}^+$  ions when the two acid concentrations are similar. The effect of HAc is particularly pronounced at higher temperatures and low pH when the abundance of undissociated HAc can increase the  $\text{CO}_2$  corrosion rate dramatically as seen in Figure 10. Solid iron acetate does not precipitate in the pH range of interest since its solubility is much higher than that of ferrous carbonate. There are some indications that the presence of organic acids impairs

**Figure 10** Predicted (line) and experimentally measured data (points) showing the effect of the concentration of undissociated acetic acid (HAc) on the  $\text{CO}_2$  corrosion rate, 60 °C,  $p_{\text{CO}_2}$  = 0.8 bar, pH 4, 12 mm OD rotating cylinder flow at 1000 rpm. Experimental data taken from Sun *et al.*<sup>20</sup>

the protectiveness of ferrous carbonate layers; however, the mechanism is still not clear.

#### 2.25.2.6.7 Effect of glycol/methanol

Glycol and methanol are often added to flowing systems in order to prevent hydrates from forming. The quantities are often significant (50% of total liquid phase is not unusual). In the very few studies available, it has been assumed that the main 'inhibitive' effect of glycol/methanol on corrosion comes from dilution of the water phase, which leads to a decreased activity of water. However, there are many unanswered questions such as the changes in mechanisms of  $\text{CO}_2$  corrosion in water/glycol mixtures which are yet to be discovered.

#### 2.25.2.6.8 Effect of condensation in wet gas flow

When transporting humid natural gas, due to the cooling of the stream, condensation of water vapor occurs on the internal pipe wall. The condensed water is pure and, due to dissolved  $\text{CO}_2$ , typically has a  $\text{pH} < 4$ . This leads to the so-called *top-of-the-line corrosion* (TLC) scenario. If the rate of condensation is high, plenty of acidic water flows down the internal pipe walls leading to a very corrosive situation. If the condensation rate is low, the water film is not renewed and flows down very slowly and the corrosion process can release enough  $\text{Fe}^{2+}$  to raise the local pH and saturate the solution, leading to the formation of protective ferrous carbonate layer. The layer is often protective; however, incidents of localized attack in TLC were reported.<sup>21</sup> Either way, the stratified or stratified-wavy flow regime, typical for TLC, does not lead to a good opportunity for inhibitors to reach the upper portion of the internal pipe wall and protect it. A very limited

range of corrosion management options for TLC exists. To qualitatively and quantitatively describe the phenomenon of corrosion occurring at the top of the line, a deep insight into the combined effect of the chemistry, hydrodynamics, thermodynamics, and heat and mass transfer in the condensed water is needed. A full description exceeds the scope of this review, and the interested reader is directed to some recent articles published on this topic.<sup>21,22</sup>

#### 2.25.2.6.9 Nonideal solutions and gases

In many cases produced, water has very high dissolved solids content (>10 wt%). At such high concentrations, the infinite dilution theory used above does not hold, and corrections need to be made to account for solution nonideality. A simple way to account for the effect on nonideal homogenous water chemistry is to correct the equilibrium constants by using the concept of ionic strength as indicated above. This approach seems to work well only for moderately concentrated solution (up to a few weight percentage of dissolved solids). For more concentrated solutions, a more accurate way is to use activity coefficients as described by Anderko *et al.*<sup>23</sup> The effect of concentrated solutions on heterogeneous reactions such as precipitation of ferrous carbonate and other layers is still largely unknown. Furthermore, it is unclear how the highly concentrated solutions affect surface electrochemistry. Some experience suggests that corrosion rates can be dramatically reduced in very concentrated brines; nevertheless a more systematic study is needed.

At very high total pressure, the gas–liquid equilibria cannot be accounted for by Henry's law. A simple correction can be made by using a fugacity coefficient, which accounts for nonideality of the CO<sub>2</sub>/natural gas mixture<sup>24</sup> and can be obtained by solving the equation of state for the gas mixture. Those cases, in which critical point for CO<sub>2</sub> is approached or exceeded, warrant a separate analysis and are not covered by the considerations discussed above.

#### 2.25.2.7 Localized CO<sub>2</sub> Corrosion of Mild Steel in Aqueous Solutions

As illustrated above, significant progress has been achieved in understanding uniform CO<sub>2</sub> corrosion, without or with protective layers, and hence successful uniform corrosion models can be built. However, much less is known about localized CO<sub>2</sub> corrosion. It is thought that one of the main factors that 'triggers' localized attack is flow, tempered by other environmental variables such as pH, temperature, partial

pressure of CO<sub>2</sub>, etc. It seems that localized attack occurs when the conditions are such that partially protective ferrous carbonate layers form. It is well known that when fully protective ferrous carbonate forms, low general corrosion rates are obtained and vice versa: when no protective layers form, a high rate of general corrosion is seen. It is when the corrosive environment is 'in between,' in the so-called 'gray zone,' that localized attack can be initiated most often by some extreme flow conditions. There are many combinations of environmental and metallurgical parameters that define the grey zone, making this sound like a difficult proposal. However, there is a single parameter which is easy to calculate: ferrous carbonate supersaturation,  $SS_{(FeCO_3)}$  (see eqn [19] above), which can be successfully used as a good delineator for the gray zone and as such a predictor for the probability for localized attack. When bulk ferrous carbonate supersaturation is in the range  $0.5 < SS_{(FeCO_3)} < 2$  there is a risk of localized attack. The further away the solution is from these boundaries, the lower the risk. The scaling tendency  $ST$  (see equation [22] above) is conceptually even better suited as a predictor of localized corrosion risk, however, its calculation is much more difficult and uncertain as it involves calculation of both the uniform corrosion rate and the precipitation rate.

Based on mostly anecdotal evidence (field experience), the presence of H<sub>2</sub>S and HAc is related to the onset of localized attack, however, little is understood about how and when this may happen.

#### 2.25.3 Aqueous H<sub>2</sub>S Corrosion of Mild Steel

Corrosion of mild steel in the presence of hydrogen sulfide (H<sub>2</sub>S) also represents a significant problem for the oil and gas industry.<sup>27–33</sup> Many fields have been developed that in addition to CO<sub>2</sub> have high concentrations of H<sub>2</sub>S. In CO<sub>2</sub>/H<sub>2</sub>S corrosion of mild steel, thermodynamic considerations suggest that both ferrous carbonate and ferrous sulfide layers could theoretically form on the steel surface. However, studies have demonstrated that the formation of the ferrous sulfide layers is dominant and presents one of the most important factors governing the H<sub>2</sub>S corrosion rate. The sulfide layer growth depends primarily on the kinetics of the corrosion process as it is described below.

Despite the relative abundance of experimental data on H<sub>2</sub>S corrosion of steel, most of the literature is still confusing and somewhat contradictory.

Therefore, the mechanism of  $\text{H}_2\text{S}$  corrosion remains much less understood when compared to that of  $\text{CO}_2$  corrosion. This uncertainty makes it more difficult to develop a model to predict the corrosion rate of mild steel in  $\text{H}_2\text{S}$  saturated aqueous solution.

### 2.25.3.1 Chemistry of $\text{H}_2\text{S}$ Saturated Aqueous Solutions – Equilibrium Considerations

Similar to  $\text{CO}_2$  discussed above,  $\text{H}_2\text{S}$  gas is also soluble in water:

**Figure 11** Calculated solubility of  $\text{H}_2\text{S}$  and  $\text{CO}_2$  as a function of temperature;  $25^\circ\text{C}$ ,  $p_{\text{H}_2\text{S}} = 1 \text{ bar}$ ,  $p_{\text{CO}_2} = 1 \text{ bar}$ .

where  $K_{\text{H}_2\text{S}}$  is the solubility constant of  $\text{H}_2\text{S}$  in  $\text{mol l}^{-1} \text{ bar}^{-1}$ :

$$K_{\text{sol}(\text{H}_2\text{S})} = \frac{c_{\text{H}_2\text{S}}}{p_{\text{H}_2\text{S}}} \quad [63]$$

and can be found from<sup>34</sup>

$$K_{\text{sol}(\text{H}_2\text{S})} = 10^{\frac{(634.27 + 0.2709 T_K - 0.11132 \times 10^{-3} T_K^2 - (16719/T_K))}{-261.9 \log T_K}} \quad [64]$$

As shown in **Figure 11**, the solubility of  $\text{H}_2\text{S}$  decreases with temperature, as it is observed for  $\text{CO}_2$ . However, for the same partial pressure and temperature, the concentration of dissolved  $\text{H}_2\text{S}$  actually exceeds that in the gas phase as shown in **Figure 12**.

Aqueous  $\text{H}_2\text{S}$  is another weak acid which partly dissociates in two steps:

where  $K_{\text{hs}}$  is the dissociation constant of  $\text{H}_2\text{S}$ :

$$K_{\text{hs}} = \frac{c_{\text{H}^+} c_{\text{HS}^-}}{c_{\text{H}_2\text{S}}} \quad [67]$$

and can be calculated as<sup>35</sup>

$$K_{\text{hs}} = 10^{\frac{782.43945 + 0.361261 T_K - 1.6722 \times 10^{-4} T_K^2 - (20565.7315/T_K)}{-142.741722 \ln T_K}} \quad [68]$$

and  $K_{\text{bs}}$  is the dissociation constant of  $\text{HS}^-$ :

**Figure 12** Calculated sulfide species concentrations as a function of pH for an  $\text{H}_2\text{S}$  saturated aqueous solution at  $p_{\text{H}_2\text{S}} = 1 \text{ mbar}$ ,  $25^\circ\text{C}$ , 1 wt% NaCl.

$$K_{bs} = \frac{c_{H^+} c_{S^{2-}}}{c_{HS^-}} \quad [69]$$

There is a very large discrepancy in the reported values for  $K_{bs}$ , varying from  $1.0 \times 10^{-19}$  to  $1.1 \times 10^{-12} \text{ kmol m}^{-3}$  at room temperature (seven orders of magnitude). In addition, these values are very small compared with other equilibrium constants, all suggesting that using  $K_{bs}$  to calculate the concentration of sulfide species,  $c_{S^{2-}}$  and further to predict the solubility product constants for ferrous sulfides should be avoided.

Given the same gaseous concentrations of  $H_2S$  and  $CO_2$ , one obtains a similar aqueous concentration of dissolved  $H_2S$  and  $CO_2$  (see Figure 11) and the resulting pH is within 0.1 pH unit, therefore, values shown in Figure 1 for  $CO_2$  can be used for  $H_2S$  as the first approximation. The equilibrium distribution of sulfide species as a function of pH for an open system is shown in Figure 12. The concentration of bisulfide ion,  $c_{HS^-}$ , becomes significant only above pH 4, while the concentration of the sulfide ion,  $c_{S^{2-}}$ , is not even shown as it is very low and unreliable to calculate.

Many types of iron sulfides, such as amorphous ferrous sulfide (FeS), mackinawite ( $Fe_{1+x}S$ ), cubic ferrous sulfide (FeS), troilite (FeS), pyrrhotite ( $Fe_{1-x}S$  or  $FeS_{1+x}$ ), smythite ( $Fe_{3+x}S_4$ ), greigite ( $Fe_3S_4$ ), and pyrite ( $FeS_2$ ) occur. Studies have suggested that some of these are stoichiometric such as cubic ferrous sulfide, troilite, greigite, and pyrite, while others such as mackinawite, pyrrhotite, and smythite are not. Some are electrically nonconductive, others apparently behave as semiconductors. However, there is no consensus on these issues and the interested reader is directed to the vast literature on iron sulfides for a more in-depth treatment. The thermodynamics of these systems is very complicated; depending on environmental conditions and time, transformation from one type of ferrous sulfide into the other occurs. Limited information exists on aqueous solubility of the various sulfides. Avoiding the usage of the sulfide ion concentration,  $c_{S^{2-}}$ , one can write a general equation for precipitation of ferrous sulfide as

where the solubility constant for one type of

ferrous sulfide – mackinawite is known as a function of temperature<sup>36,37</sup>

$$K_{sp(FeS)}^{mackin} = 10^{(2848.779)/T_k - 6.347} \quad [71]$$

For other ferrous sulfides, only the values at room temperature are known, as listed in Table 1 below. It is convenient to show various ferrous sulfide solubilities in terms of an equilibrium concentration of the  $Fe^{2+}$  as a function of pH at a given  $H_2S$  partial pressure (concentration). An example is presented in Figure 13 where it can be seen that the much less soluble pyrrhotite and troilite are thermodynamically more stable forms compared to mackinawite and amorphous ferrous sulfide. For a typical ferrous ion concentration of  $c_{Fe^{2+}} = 1 \text{ ppm}$ , the saturation with respect to troilite and pyrrhotite is reached already at pH 5.4, while for mackinawite it is pH 6 and for amorphous ferrous sulfide pH 6.7. Keeping in mind that the concentration of  $Fe^{2+}$  at a corroding steel surface can easily be much higher than in the bulk (e.g., 10 ppm or even higher) and that the pH is also higher at the surface than in the bulk (typically above pH 6), using Figure 13 one can expect a whole range of different ferrous sulfides to form on a corroding steel surface at this  $H_2S$  concentration at different points in time.

SEM images of a ferrous sulfide surface layer formed on mild steel after a week long exposure are shown in Figure 14. The layered structure of the sulfide is prominent, and it can be identified as mackinawite. In longer exposures, the ferrous sulfide layer thickens and eventually becomes more protective. An image of a ferrous sulfide layer after a month long exposure is shown in Figure 15. The composition of the layer is a mixture of mackinawite and pyrrhotite. Another layered structure composed of a mixture of ferrous carbonate and ferrous sulfide is shown in Figure 16.

**Table 1** Solubility product constants for various ferrous sulfides at 25 °C<sup>38</sup>

Type of ferrous sulfide	$-\log K_{sp(FeS)}$
Amorphous (FeS)	2.95
Mackinawite ( $Fe_{1+x}S$ )	3.6
Pyrrhotite ( $Fe_{1-x}S$ or $FeS_{1+x}$ )	5.19
Troilite (FeS)	5.31

**Figure 13** Calculated solubility of various iron sulfides as a function of pH shown in terms of the equilibrium concentration of  $\text{Fe}^{2+}$ ,  $p_{\text{H}_2\text{S}} = 1 \text{ mbar}$ ,  $25^\circ\text{C}$ ,  $1 \text{ wt\% NaCl}$ .

**Figure 14** SEM images showing a cross-section and a top view of a ferrous sulfide layer formed on mild steel;  $60^\circ\text{C}$ ,  $\text{pH } 6$ ,  $p_{\text{CO}_2} = 7.7 \text{ bar}$ ,  $p_{\text{H}_2\text{S}} = 0.25 \text{ mbar}$ ,  $1 \text{ m s}^{-1}$  single phase flow in a  $100 \text{ mm ID}$  pipe, 7 days exposure.

**Figure 15** SEM images showing a cross-section view of a ferrous sulfide layer formed on mild steel;  $60^\circ\text{C}$ ,  $\text{pH } 6$ ,  $p_{\text{CO}_2} = 7.7 \text{ bar}$ ,  $p_{\text{H}_2\text{S}} = 0.25 \text{ mbar}$ ,  $1 \text{ m s}^{-1}$  single phase flow in a  $100 \text{ mm ID}$  pipe, 30 day exposure.

### 2.25.3.2 Mild Steel Corrosion in $\text{H}_2\text{S}$ and Mixed $\text{H}_2\text{S}/\text{CO}_2$ Saturated Aqueous Solutions

As aqueous  $\text{H}_2\text{S}$  is another weak acid, it can be seen as an additional reservoir of  $\text{H}^+$  ions according to reaction [65], similar to  $\text{H}_2\text{CO}_3$ . Therefore, stimulation of the hydrogen evolution reaction could also be expected in the presence of  $\text{H}_2\text{S}$ . Using the analogy with  $\text{CO}_2$  corrosion, one must also allow the possibility of direct reduction of  $\text{H}_2\text{S}$ , that is, that the  $\text{H}_2\text{S}$  molecule can be adsorbed at the steel surface,

**Figure 16** SEM images showing a cross-section view of a mixed ferrous carbonate and ferrous sulfide layer formed on mild steel; 60 °C, pH 6,  $p_{\text{CO}_2} = 7.7$  bar,  $p_{\text{H}_2\text{S}} = 1.2$  mbar,  $1 \text{ m s}^{-1}$  single phase flow in a 100 mm ID pipe, 25 day exposure.

followed by a reduction of the  $\text{H}^+$  and oxidation of iron in the steel. One can write the overall corrosion reaction as

As solid ferrous sulfide (mackinawite) is always found on the corroding steel surface in the presence of  $\text{H}_2\text{S}$ , even below the solubility limit, this can be referred to as a direct ‘solid state’ reaction pathway as both the initial and final state of Fe are solid(s).<sup>39</sup>

Experimental evidence suggests that corrosion of mild steel by  $\text{H}_2\text{S}$  initially proceeds by adsorption of  $\text{H}_2\text{S}$  to the steel surface followed by a very fast redox reaction at the steel surface to form an adherent mackinawite film (much like a tarnish). This initial mackinawite film is very thin ( $\ll 1 \mu\text{m}$ ) but apparently rather dense and acts as a solid state diffusion barrier for the species involved in the corrosion reaction. Therefore, this thin mackinawite film is one of the most important factors governing the corrosion rate in  $\text{H}_2\text{S}$  corrosion. It also impedes the mobility of other species in reaching the steel surface and therefore corrosion rates due to  $\text{CO}_2$  are affected even if very small amounts of  $\text{H}_2\text{S}$  are present in the gas phase (as little as  $10^{-5}$  bar).

The thin mackinawite film continuously goes through a cyclic process of growth, internal stress growth, cracking, and delamination that generates an outer sulfide layer, which thickens over time (typically  $\gg 1 \mu\text{m}$ ) and forms an additional diffusion barrier. However, this outer sulfide layer is very porous and rather loosely attached to the steel surface. Over time it cracks, peels, and spalls, a process accelerated by turbulent flow. If the pH

of the solution is below saturation level, the outer sulfide layer will undergo a process of chemical dissolution. Conversely, when the saturation is exceeded, ferrous sulfide precipitation from the bulk is possible. Eventually, the amount and protectiveness of the outer sulfide layer is determined by the balance of the various formation and removal processes.<sup>39</sup>

The transformation of mackinawite into other forms of less soluble and more stable ferrous sulfide (pyrrhotite and troilite, see Figure 13) may happen over time. Among the various ferrous sulfides, mackinawite is the prevalent ferrous sulfide that forms in the corrosion of mild steel at low  $\text{H}_2\text{S}$  concentration and low temperature. At increased levels of  $\text{H}_2\text{S}$ , mackinawite is less prevalent and pyrrhotite is the main corrosion product. At very high  $\text{H}_2\text{S}$  concentrations, pyrite and elemental sulfur appear. While thermodynamics of ferrous sulfides may favor other types of sulfide over mackinawite as the corrosion product, the rapid kinetics of mackinawite formation favors it as the initial corrosion product seen in most situations. Overall, however, there is currently no clearly defined relationship between the nature of the sulfide layer and the underlying corrosion process. It is generally thought that all types of ferrous sulfide layers offer some degree of corrosion protection for mild steel.

At very high  $\text{H}_2\text{S}$  concentrations, elemental sulfur can appear and lead to severe localized corrosion. Large amounts of elemental sulfur can precipitate out of the gas stream and can even block the line, due to the changes in pressure and temperature. Alternatively, when there is  $\text{O}_2$  present, the most likely pathways for formation of elemental sulfur are as follows:

- ferrous sulfide reacts with  $\text{O}_2$  and converts to iron oxide forming elemental sulfur probably via:

- at very high  $\text{H}_2\text{S}$  concentration, the following reaction can occur to yield elemental sulfur:

At very high temperatures, an alternative pathway is

Localized corrosion by elemental sulfur occurs via a reaction with the iron in the steel, represented by the

overall reaction

It is not very clear at this stage what the detailed mechanism of this reaction is. It appears that rapid attack is seen only when direct contact of sulfur with the steel is achieved in the presence of water. A more in-depth discussion about the corrosion mechanisms of mild steel involving elemental sulfur exceeds the scope of this review.

### 2.25.3.3 Calculation of Mild Steel H<sub>2</sub>S Corrosion Rate

Due to the complexity of the underlying processes and a lack of mechanistic understanding, predictive models of H<sub>2</sub>S corrosion were not readily available until recently. One approach<sup>40</sup> which has the capability to address a few simple H<sub>2</sub>S corrosion scenarios is presented below. A pure H<sub>2</sub>S corrosion environment is described first followed by a mixed H<sub>2</sub>S/CO<sub>2</sub> corrosion scenario.

#### 2.25.3.3.1 Pure H<sub>2</sub>S aqueous environment

Due to the presence of the inner mackinawite film and the outer porous sulfide layer, it is assumed that the corrosion rate of steel in H<sub>2</sub>S solutions is always under mass transfer control. One can then write the flux of H<sub>2</sub>S due to:

- convective diffusion through the mass transfer boundary layer as

$$\text{Flux}_{\text{H}_2\text{S}} = k_{\text{m}(\text{H}_2\text{S})} (c_{\text{H}_2\text{S}} - c_{\text{o}(\text{H}_2\text{S})}) \quad [77]$$

- molecular diffusion through the liquid in the porous outer sulfide layer as

$$\text{Flux}_{\text{H}_2\text{S}} = \frac{D_{\text{H}_2\text{S}} \varepsilon \psi}{\delta_{\text{os}}} (c_{\text{o}(\text{H}_2\text{S})} - c_{\text{i}(\text{H}_2\text{S})}) \quad [78]$$

- solid state diffusion through the inner mackinawite film as

$$\text{Flux}_{\text{H}_2\text{S}} = A_{\text{H}_2\text{S}} \exp\left(-\frac{B_{\text{H}_2\text{S}}}{RT_k}\right) \ln\left(\frac{c_{\text{i}(\text{H}_2\text{S})}}{c_{\text{s}(\text{H}_2\text{S})}}\right) \quad [79]$$

In a steady state, the three fluxes are equal to each other and are equivalent to the corrosion rate as

$$\text{CR}_{\text{H}_2\text{S}} = \text{Flux}_{\text{H}_2\text{S}} M_{\text{Fe}} / \rho_{\text{Fe}} \quad [80]$$

further corrected for appropriate corrosion rate unit.

By eliminating the unknown interfacial concentrations  $c_{\text{o}(\text{H}_2\text{S})}$  and  $c_{\text{i}(\text{H}_2\text{S})}$  from eqns [77] to [79], the following equation is obtained for the flux (corrosion rate) due to H<sub>2</sub>S:

$$\text{Flux}_{\text{H}_2\text{S}} = A_{\text{H}_2\text{S}} \ln \frac{c_{\text{H}_2\text{S}} - \text{Flux}_{\text{H}_2\text{S}} \left( \frac{\delta_{\text{os}}}{D_{\text{H}_2\text{S}} \varepsilon \psi} + \frac{1}{k_{\text{m}(\text{H}_2\text{S})}} \right)}{c_{\text{s}(\text{H}_2\text{S})}} \quad [81]$$

This is an algebraic nonlinear equation with respect to  $\text{Flux}_{\text{H}_2\text{S}}$ , which does not have an explicit solution but can be solved by using a simple numerical algorithm such as the interval halving method or similar methods. These are available as ready-made routines in spreadsheet applications or in any common computer programming language. The prediction for  $\text{Flux}_{\text{H}_2\text{S}}$  depends on a number of constants used in the model which can be either found in handbooks (such as  $D_{\text{H}_2\text{S}}$ ), calculated from the established theory (e.g.,  $k_{\text{m}(\text{H}_2\text{S})}$ ) or are determined from experiments (e.g.,  $A_{\text{H}_2\text{S}}$ ,  $c_{\text{s}(\text{H}_2\text{S})}$ ). The unknown thickness of the outer sulfide layer change with time and need to be calculated as described below.

It is assumed that the amount of layer retained on the metal surface at any point in time depends on the balance of:

- layer formation kinetics (as the layer is generated by spalling of the thin mackinawite film underneath it and by the precipitation from the solution), and
- layer damage kinetics (as the layer is damaged by intrinsic or hydrodynamic stresses and/or by chemical dissolution):

$$\underbrace{\text{SRR}}_{\text{Sulfide layer retention rate}} = \underbrace{\text{SFR}}_{\text{Sulfide layer formation rate}} - \underbrace{\text{SDR}}_{\text{Sulfide layer damage rate}} \quad [82]$$

where all the terms are expressed in  $\text{kmol m}^{-2} \text{s}^{-1}$ . In order to simplify the calculations, it can be assumed that in the typical range of application ( $4 < \text{pH} < 7$ ), precipitation and dissolution of ferrous sulfide layer do not play a significant role and so it can be written

$$\text{SRR} = \text{CR} - \text{SDR}_{\text{m}} \quad [83]$$

Some experiments involving mackinawite have shown that even in stagnant conditions about half of the outer sulfide layer that forms is lost from the steel surface due to intrinsic growth stresses by internal cracking and spalling, that is,  $\text{SDR}_{\text{m}} \approx 0.5\text{CR}$ , so one obtains:

$$\text{SRR} = 0.5\text{CR} \quad [84]$$

that is, about half of the iron corroded is found on the steel surface in the form of mackinawite. It is not known if and how this ratio is different when other types of ferrous sulfide layers form, for example, the more adherent and protective pyrrhotite. Moreover, additional experimentation is required to determine how the mechanical layer damage is affected by hydrodynamic forces.

Once the layer retention rate SRR is known, the change in mass of the outer sulfide layer can be easily calculated as

$$\Delta m_{os} = SRR M_{FeS} A \Delta t \quad [85]$$

The porosity of the outer sulfide layer was determined to be very high ( $\varepsilon \approx 0.9$ ) by comparing the weight of the layer with the cross-sectional SEM images showing its thickness. On the other hand, this layer has proven to be rather protective (i.e., impermeable to diffusion) which can only be explained by its low tortuosity arising from its layered structure. By comparing the measured and calculated corrosion rates in the presence of the outer sulfide layer, the tortuosity factor was calculated to be  $\psi = 0.003$ .

A time-marching explicit solution procedure could now be established where

1. the corrosion rate  $\text{Flux}_{H_2S}$  in the absence of outer sulfide layer can be calculated by using eqn [81], and assuming  $\delta_{os} = 0$ ;
2. the amount of sulfide layer  $\delta m_{os}$  formed over a time interval  $\Delta t$  is calculated by using eqn [85];
3. the new corrosion rate  $\text{Flux}_{H_2S}$  in the presence of sulfide layer can be recalculated by using eqn [81];
4. a new time interval  $\Delta t$  is set and steps 2 and 3 repeated.

At very low  $H_2S$  gas concentrations (ppm<sub>w</sub> range), there is very little dissolved  $H_2S$  and the corrosion rate is directly affected by pH. A mackinawite layer still forms and controls the corrosion rate; however, the corrosion process is largely driven by the reduction of  $H^+$  ions, rather than of  $H_2S$ . By analogy with the approach laid out above, the following expression is obtained for the flux of  $H^+$  ions controlled by the presence of the ferrous sulfide layers:

$$\text{Flux}_{H^+} = A_{H^+} \ln \frac{c_{H^+} - \text{Flux}_{H^+} \left( \frac{\delta_{os}}{D_{H^+} \varepsilon \psi} + \frac{1}{k_m(H^+)} \right)}{c_s(H^+)} \quad [86]$$

The flux  $\text{Flux}_{H^+}$  is directly related to the corrosion rate by  $H^+$  ions:

$$CR_{H^+} = \frac{\text{Flux}_{H^+} M_{Fe}}{2 \rho_{Fe}} \quad [87]$$

further adjusted for the appropriate corrosion rate unit.

By solving eqns [81] and [86] sequentially in time, the total corrosion rate in mixed pure  $H_2S$  aqueous environments can be calculated as

$$CR = CR_{H_2S} + CR_{H^+} \quad [88]$$

### 2.25.3.3.2 Mixed $CO_2/H_2S$ environments

For mild steel corrosion in mixed  $CO_2/H_2S$  containing environments, one can account for the effect of  $CO_2$  by assuming that the rate controlling step in this additional process is the diffusion of  $CO_2$  through the ferrous sulfide layers. Then a similar expression can be obtained for the corrosion rate due to  $CO_2$ :

$$\text{Flux}_{CO_2} = A_{CO_2} \ln \frac{c_{CO_2} - \text{Flux}_{CO_2} \left( \frac{\delta_{os}}{D_{CO_2} \varepsilon \psi} + \frac{1}{k_m(CO_2)} \right)}{c_s(CO_2)} \quad [89]$$

The flux  $\text{Flux}_{CO_2}$  is equivalent to the corrosion rate by  $CO_2$ :

$$CR_{CO_2} = \frac{\text{Flux}_{CO_2} M_{Fe}}{2 \rho_{Fe}} \quad [90]$$

further adjusted for appropriate corrosion rate unit.

By solving eqns [81], [86], and [89], the total corrosion rate in mixed  $CO_2/H_2S$  environments can be calculated as

$$CR = CR_{H_2S} + CR_{H^+} + CR_{CO_2} \quad [91]$$

### 2.25.3.4 Limitations of Modeling of Aqueous $H_2S$ Corrosion of Mild Steel

The calculation model presented above covers uniform  $H_2S$  and  $CO_2/H_2S$  corrosion. There are numerous limitations:

- It does not predict localized corrosion in either environment.
- While it covers a very broad range of  $H_2S$  partial pressures, it is not recommended to use this model below  $p_{H_2S} = 0.01$  mbar or above  $p_{H_2S} = 10$  bar. Similar limits apply to the  $CO_2$  partial pressure.

This leaves a very broad area of applicability for the present model.

- This H<sub>2</sub>S model does not account for any precipitation of ferrous sulfide, ferrous carbonate, or any other scale; therefore, in cases where this is deemed important for corrosion, the model should be used with caution. The model also does not account for various transformations of sulfide layer from one type to another which are known to happen over time.
- The present model does not account for dissolution of the sulfide layer that may occur at very low pH. Therefore, the use of this model at pH < 3 is not recommended. Similarly, the model should be used with caution for pH > 7 where it has not been tested.
- The model in its present state does not cover the effect of organic acids on mixed H<sub>2</sub>S and CO<sub>2</sub>/H<sub>2</sub>S corrosion, and therefore it should not be used when organic acids are present in the system. A practical threshold for the validity of the present model is <1 ppm of organic acids in the brine.
- The model does not account for the effect of high chloride concentrations, oxygen, elemental sulfur or any other unspecified condition, which is known to affect the corrosion rate and is not explicitly covered in the theoretical underpinnings discussed above.

While this calculation model is clearly not inclusive of all the important processes in aqueous H<sub>2</sub>S corrosion of mild steel, it is believed that the

main underlying assumptions about the formation and protective nature of a mackinawite layer are correct. The comparison of the performance of this model with experimental data is given in the following section, which covers the main factors affecting CO<sub>2</sub>/H<sub>2</sub>S corrosion of mild steel.

### 2.25.3.5 Key Factors Affecting Aqueous H<sub>2</sub>S Corrosion of Mild Steel

Some of the key factors affecting aqueous H<sub>2</sub>S corrosion are discussed in these sections, and the experimental results are compared with the model described above.

#### 2.25.3.5.1 Effect of H<sub>2</sub>S partial pressure

Corrosion rate of mild steel at extremely low H<sub>2</sub>S partial pressures is seen in Figure 17 wherein atmospheric glass cell experiments  $p_{\text{H}_2\text{S}}$  ranged from 0.0013–0.32 mbar, corresponding to 1–250 ppm<sub>m</sub> in the gas phase at 1 bar CO<sub>2</sub>. Clearly, this is a CO<sub>2</sub> dominated corrosion scenario ( $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio is in the range  $10^3$ – $10^6$ ); however, the presence of H<sub>2</sub>S controls the corrosion rate. Even when present in such minute amounts, H<sub>2</sub>S reduces the pure CO<sub>2</sub> (H<sub>2</sub>S-free) corrosion rate by 3–10 times due to the formation of a thin mackinawite film. The model presented above successfully captures this effect as shown in Figure 17.

At higher H<sub>2</sub>S partial pressures, the same effect is observed as shown in Figure 18, which shows results from autoclave experiments conducted at a very high

**Figure 17** The corrosion rate vs. partial pressure of H<sub>2</sub>S; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; conditions: total pressure  $p = 1$  bar,  $p_{\text{CO}_2} = 1$  bar,  $p_{\text{H}_2\text{S}} = 0.0013$ – $0.32$  mbar,  $T = 20^\circ\text{C}$ , reaction time 24 h, pH 5, 1000 rpm. For reference: pure CO<sub>2</sub> corrosion rate is measured to be  $1\text{ mm year}^{-1}$ . Data taken from Lee.<sup>41</sup>

total pressure ( $p = 138$  bar) and a high  $\text{CO}_2$  partial pressure ( $p_{\text{CO}_2} = 13.8$  bar). When comparing the predictions with the experimental results, it can be seen that the model underpredicts the observed rate of steel corrosion by approximately a factor of 2. However, when this is compared with a pure  $\text{CO}_2$  ( $\text{H}_2\text{S}$ -free) corrosion rate under the same conditions (which is not reported but can be predicted to be almost  $20 \text{ mm year}^{-1}$ ), the accuracy of the model can be considered as reasonable. At the highest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$

ratio of 3500 ( $p_{\text{CO}_2} = 13.8$  bar,  $p_{\text{H}_2\text{S}} = 40$  mbar),  $\text{CO}_2$  accounts for  $\sim 70\%$  of the corrosion rate and 30% can be ascribed to  $\text{H}_2\text{S}$ . At the lowest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 1180 ( $p_{\text{CO}_2} = 13.8$  bar,  $p_{\text{H}_2\text{S}} = 116$  mbar),  $\text{CO}_2$  accounts for  $\sim 57\%$  of the corrosion rate and 43% can be ascribed to  $\text{H}_2\text{S}$ .

Corrosion rates of mild steel at very high partial pressures of  $\text{H}_2\text{S}$  ( $p_{\text{H}_2\text{S}} = 3\text{--}20$  bar) and  $\text{CO}_2$  ( $p_{\text{CO}_2} = 3\text{--}12.8$  bar) for exposures lasting up to 4 days are shown in Figure 19. This is a situation where the

**Figure 18** The corrosion rate vs.  $\text{H}_2\text{S}$  partial pressure; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; conditions: total pressure  $p = 137.9$  bar,  $p_{\text{CO}_2} = 13.8$  bar,  $p_{\text{H}_2\text{S}} = 40\text{--}120$  mbar,  $T = 50^\circ\text{C}$ , experiment duration 3 days, pH 4.0–6.2, stagnant. Experimental data taken from Smith and Pacheco *et al.*<sup>31</sup>

**Figure 19** The corrosion rate vs. time; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; Test A and B:  $p = 8.3$  bar,  $p_{\text{CO}_2} = 5.3$  bar,  $p_{\text{H}_2\text{S}} = 3$  bar,  $T = 60^\circ\text{C}$ , 71 h (a) and 91 h (b); Test C:  $p = 24$  bar,  $p_{\text{CO}_2} = 4$  bar,  $p_{\text{H}_2\text{S}} = 20$  bar,  $T = 70^\circ\text{C}$ , 91 h; Test D:  $p = 15.7$  bar,  $p_{\text{CO}_2} = 3.5$  bar,  $p_{\text{H}_2\text{S}} = 12.2$  bar,  $T = 65^\circ\text{C}$ , 69 h; Test E:  $p = 20.8$  bar,  $p_{\text{CO}_2} = 12.8$  bar,  $p_{\text{H}_2\text{S}} = 8$  bar,  $T = 65^\circ\text{C}$ , 91 h; Test F:  $p = 7.2$  bar,  $p_{\text{CO}_2} = 3$  bar,  $p_{\text{H}_2\text{S}} = 4.2$  bar,  $T = 65^\circ\text{C}$ , 63 h; experimental data taken from Bich and Goerz.<sup>43</sup>

H<sub>2</sub>S was the dominant corrosive species. At the highest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 1.8 ( $p_{\text{CO}_2} = 5.3$  bar,  $p_{\text{H}_2\text{S}} = 3$  bar), H<sub>2</sub>S generated ~86% of the corrosion rate. At the lowest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 0.2 ( $p_{\text{CO}_2} = 4$  bar,  $p_{\text{H}_2\text{S}} = 20$  bar), H<sub>2</sub>S generated 97% of the overall corrosion rate. It is also noted that the model predictions show that the corrosion rate in the first reaction hour is on average 20 mm year<sup>-1</sup> with an initial corrosion rate of 60 mm year<sup>-1</sup> and a final corrosion rate of 10 mm year<sup>-1</sup>. The pitting corrosion rate was reported to be 30 mm year<sup>-1</sup> in a field case with similar conditions, which is related to the very high, H<sub>2</sub>S-driven corrosion seen at the beginning of experiments before a thick protective ferrous sulfide film forms.

### 2.25.3.5.2 Effect of flow

The effect of flow velocity in H<sub>2</sub>S corrosion is shown in Figure 20 for the three long-term experiments reported by Omar *et al.*<sup>44</sup> Flow loop experiments lasting 15–21 days were conducted at severe conditions: high partial pressure of H<sub>2</sub>S ( $p_{\text{H}_2\text{S}} = 10$ –30 bar), high partial pressure of CO<sub>2</sub> ( $p_{\text{CO}_2} = 3.3$ –10 bar) and low pH 2.9–3.2. No effect of velocity on the uniform corrosion rate could be observed in these long-term exposures, which is due to the build-up of a thick protective sulfide layer. The model predictions also shown in Figure 20 confirm this trend and show a remarkable agreement with the experimental results

in the less extreme experiments 1 and 2 ( $p_{\text{CO}_2} = 3.3$  bar;  $p_{\text{H}_2\text{S}} = 10$  bar) both at low (25 °C) and high temperature (80 °C). In experiment 3 which was conducted at the most extreme set of conditions ( $p_{\text{CO}_2} = 10$  bar;  $p_{\text{H}_2\text{S}} = 30$  bar) and high temperature (80 °C) the model overpredicts the corrosion rate by a factor of 2.5. In all three experiments reported by Omar *et al.*,<sup>44</sup> the  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio was about 0.3, that is, the corrosion process and corrosion rate were completely dominated by H<sub>2</sub>S, which contributed ~95% of the corrosion rate.

### 2.25.3.5.3 Effect of time

A marked decrease of corrosion rate with time was seen in autoclave tests as reported in Figure 19 above; the same was observed in stratified pipe flow experiments where pure CO<sub>2</sub> corrosion rate decreased with time due to the presence of H<sub>2</sub>S, as shown in Figure 21 below. The latter is also a mixed CO<sub>2</sub>/H<sub>2</sub>S corrosion scenario. At a  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 200 ( $p_{\text{CO}_2} = 2$  bar,  $p_{\text{H}_2\text{S}} = 4$  mbar), the CO<sub>2</sub> contribution to the corrosion rate is 75% with most of the balance provided by H<sub>2</sub>S. At the  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 28 ( $p_{\text{CO}_2} = 2$  bar,  $p_{\text{H}_2\text{S}} = 70$  mbar), both CO<sub>2</sub> and H<sub>2</sub>S account for ~50% of the overall corrosion rate.

Corrosion experiments at high temperature (120 °C), high partial pressures of CO<sub>2</sub> ( $p_{\text{CO}_2} = 6.9$  bar), and H<sub>2</sub>S ( $p_{\text{H}_2\text{S}} = 1.38$ –4.14 bar) in exposures

**Figure 20** The corrosion rate vs. velocity; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; exp 1.: 19 days,  $p = 40$  bar,  $p_{\text{CO}_2} = 3.3$  bar,  $p_{\text{H}_2\text{S}} = 10$  bar,  $T = 80$  °C, pH 3.1,  $v = 1$ –5 m s<sup>-1</sup>; exp 2.: 21 days,  $p = 40$  bar,  $p_{\text{CO}_2} = 3.3$  bar,  $p_{\text{H}_2\text{S}} = 10$  bar,  $T = 25$  °C, pH 3.2,  $v = 1$ –5 m s<sup>-1</sup>; exp 3.: 10 days,  $p = 40$  bar,  $p_{\text{CO}_2} = 10$  bar,  $p_{\text{H}_2\text{S}} = 30$  bar,  $T = 80$  °C, pH 2.9,  $v = 1$ –5 m s<sup>-1</sup>; experimental data taken from Omar *et al.*<sup>44</sup>

**Figure 21** The corrosion rate vs. time; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; conditions: total pressure  $p = 3$  bar,  $p_{\text{CO}_2} = 2$  bar,  $p_{\text{H}_2\text{S}} = 3\text{--}70$  mbar,  $T = 70^\circ\text{C}$ , experiment duration 2–21 days, pH 4.2–4.9, liquid velocity  $0.3\text{ m s}^{-1}$ . Experimental data taken from Singer *et al.*<sup>42</sup>

**Figure 22** The corrosion rate vs. time; experimental data (exp.) shown as points, model predictions (mod.) shown as lines; conditions: total pressure  $p = 7$  bar,  $p_{\text{CO}_2} = 6.9$  bar,  $p_{\text{H}_2\text{S}} = 1.38\text{--}4.14$  bar,  $T = 120^\circ\text{C}$ , experiment duration 1–16 days, pH 3.95–4.96, liquid velocity  $10\text{ m s}^{-1}$ . Experimental data taken from Kvarekval *et al.*<sup>45</sup>

lasting up to 16 days are shown in Figure 22. A steadily decreasing corrosion rate was observed due to build-up of a protective ferrous sulfide layer. The effect of  $p_{\text{H}_2\text{S}}$  increase on corrosion rate was very small and practically vanished over time. Both these effects were readily captured by the model with very good accuracy as seen in Figure 22. In this case, the  $\text{H}_2\text{S}$  is the dominant corrosive species. At the highest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 5 ( $p_{\text{CO}_2} = 6.9$  bar,  $p_{\text{H}_2\text{S}} = 1.38$  bar),  $\text{H}_2\text{S}$  generated  $\sim 70\%$  of the corrosion rate. At the

lowest  $p_{\text{CO}_2}/p_{\text{H}_2\text{S}}$  ratio of 1.67 ( $p_{\text{CO}_2} = 6.9$  bar,  $p_{\text{H}_2\text{S}} = 4.14$  bar),  $\text{H}_2\text{S}$  generated 82% of the overall corrosion rate.

The longest  $\text{H}_2\text{S}$  containing corrosion experiments which are practically achievable in the lab are of the order of a few weeks or at best a few months, while predictions are meant to cover a period of at least a decade, in order to be meaningful. With this in mind, it is interesting to take the experimental conditions above ( $p_{\text{CO}_2} = 6.9$  bar,  $p_{\text{H}_2\text{S}} = 3.45$  bar,

**Figure 23** Extension of corrosion prediction to a 25-year lifetime; experimental (points), predicted (lines); conditions:  $p_{\text{CO}_2} = 6.9$  bar,  $p_{\text{H}_2\text{S}} = 3.45$  bar,  $T = 120^\circ\text{C}$ , pH 4, liquid velocity  $10\text{ m s}^{-1}$ . Data from Kvarekval *et al.*<sup>45</sup>

$T = 120^\circ\text{C}$ , pH 4,  $v = 10\text{ m s}^{-1}$ ) and extend the simulation to 25 years. The result is shown in Figure 23. The corrosion rate was predicted to start out rather high as observed in the experiments; however, it was reduced to below  $0.1\text{ mm year}^{-1}$  after 2 years and was as low as  $0.03\text{ mm year}^{-1}$  after 25 years. The average corrosion rate over this period was only  $0.06\text{ mm year}^{-1}$ , which amounts to a wall thickness loss of only 1.5 mm over the 25 years, an acceptable amount by any practical account. Actually, most of the other conditions simulated have shown that rather low  $\text{H}_2\text{S}$  uniform corrosion rates are obtained for very long exposures, which agrees with general field experience as recently discussed by Bonis *et al.*<sup>33</sup> Nevertheless, no quantitative long-term lab data are currently available to back-up these long-term predictions, and therefore they should be used with caution.

#### 2.25.3.6 Localized $\text{H}_2\text{S}$ Corrosion of Mild Steel in Aqueous Solutions

Localized  $\text{H}_2\text{S}$  corrosion of mild steel is even less understood than its uniform counterpart. While it is not very common, anecdotal evidence exists that has linked localized  $\text{H}_2\text{S}$  corrosion in aqueous environments to other factors such as high chloride content, the presence of elemental sulfur and the transformation of one type of sulfide into another. Intense research of these topics is ongoing with a breakthrough in understanding expected in the decade to come.

### Glossary

**Aromatic** A hydrocarbon containing one or more conjugated (i.e., repeated single and double) bonds in the form of a ring (e.g., benzene – C<sub>6</sub>H<sub>6</sub>).

**Asphaltenes** Molecular substances found in crude oil that have some of the properties of asphalt, with high viscosity and melting point. Practically they are defined as crude oil fractions that are generally insoluble in *n*-heptane (C<sub>7</sub>H<sub>14</sub>) but soluble in toluene (CH<sub>3</sub>·C<sub>6</sub>H<sub>5</sub>).

**Grease** A solid or semi-solid lubricant material that consists of calcium, sodium or lithium soap that is emulsified with mineral or vegetable oil.

**Oligomer** A compound containing a limited (generally small) number of monomer units (as opposed to a polymer, which in principle contains a large number of monomer units).

**Olefin** A hydrocarbon that contains unsaturated bonds (e.g., ethene – C<sub>2</sub>H<sub>4</sub>).

**Paraffin** A hydrocarbon that contains no unsaturated bonds (e.g., ethane – C<sub>2</sub>H<sub>6</sub>).

**Soap** A metallic salt of a fatty acid.

Lubricants and fuels are not generally regarded as being corrosive, and therefore, in order to appreciate how corrosion can occur in lubricant systems, it is necessary to understand something of their nature. Once lubricants were almost exclusively derived from animal (e.g., whale) or vegetable (e.g., castor) oils or fats but modern requirements by way of volume and special properties have made petroleum the main source of supply. The production of lubricants represents between 1 and 2% of all petroleum products by volume but considerably more by value and type.

The main function of most lubricants is to reduce friction and wear between moving surfaces and to abstract heat. They also have to remove debris from the contact area (e.g., combustion products in an engine cylinder) or swarf in metal-cutting operations (e.g., in metal-working fluids). They may also be required to protect the lubricated or adjacent parts against corrosion, but this is not a prime function of most lubricants. On the other hand, many lubricants do contain corrosion inhibitors and some lubricating oils, greases, mineral fluids, and compounds are specially formulated to prevent the corrosion of machinery or machine parts, particularly when these components are in storage or in transit (e.g., temporary protectives).

**2.26.1.2 Lubricating Oils**

There are many hundreds of different varieties of lubricants, many of them tailored to meet specific requirements. For some applications, vegetable oils (especially those derived from the castor oil plant) are still preferred. However, due to the volume requirements petroleum-derived (mineral) lubricant base oil stocks predominate.<sup>1</sup>

Mineral base oils may be distillates or from residues and are derived from the vacuum distillation of a primary distillate with a boiling point range generally above that of gas oils (i.e., above about 200°C). They are mixtures of hydrocarbons, generally containing more than about 20 carbon atoms per molecule, and range from thin, easily flowing long-chain ‘spindle’ molecules to thick, branched, ‘cylinder’ oils. For hydrocarbons having the same number of carbon atoms per molecule, generally, the higher the proportion of carbon to hydrogen, the more viscous the oil and the lower the viscosity index.

Distillate lubricating oils can be conveniently divided into three groups: low viscosity index oils (LVI oils), medium viscosity index oils (MVI oils), and high viscosity index oils (HVI oils). LVI oils are made from naphthenic distillates with low wax contents so that costly dewaxing is not required. MVI oils are produced from both naphthenic and paraffinic distillates; generally, the paraffinic distillates have to be dewaxed (i.e., those fractions that are solid at room temperature need to be removed from the base oil). The residues from the vacuum distillation can also be refined to provide very viscous lubricants; thus, residues from paraffinic base oils are generally solvent extracted and dewaxed. The main use of these products (bright stocks) is as blending components for heavy lubricants.

The mineral base oil fractions may be further categorized as predominantly long-chain aliphatic (paraffinic) hydrocarbons or aromatic hydrocarbons, depending on the crude feedstock. For higher performance, base oils may be synthesized to produce a more tightly specified range of compounds such as olefin oligomers and polyolefinic aromatics that are not present in the original crude oil feedstock. Although such materials can cost 5–10 times more than the conventional materials, their properties are more predictable and their performance (e.g., thermal and chemical stability) is significantly improved.

The primary component of a lubricant, which commonly comprises over 70% and generally up to 98% of the volume of the material, is the base oil stock. To this are added further components that modify and improve the overall performance of the lubricant for specific purposes. Additives that are present in most formulations include: viscosity modifiers, detergents and dispersants, antifoaming agents, oxidation inhibitors, and corrosion inhibitors (often called ‘rust inhibitors’). Additives for specific purposes include biocides and antiwear and extreme pressure (EP) components, which are formulated to react with metal bearing surfaces under extreme conditions to produce a low friction surface.

### 2.26.1.3 Greases

Greases, in contrast to oils, are solid or semisolid lubricants that are made by thickening lubricating base oils with gelling agents such as metal ion salts of long-chain fatty acids (i.e., soaps), lubricious solids such as talc, mica, graphite, and molybdenum disulfide, as well as the conventional additives mentioned above. Typical greases are formulated from approximately a 1:1 ratio of lubricating base oil with emulsifying agent (usually calcium, sodium, or lithium soaps of long-chain fatty acids) plus additives. Greases are used where lubrication may be infrequent and/or where the lubricant is required to remain in place over a significant length of time. Greases are essentially emulsions of the base oil with the soap as the emulsifying agent and second phase and are thixotropic; that is under high shear the viscosity falls to values more representative of the base oil used in the formulation. Thus, they are ideal for lubrication of bearings and similar components. Since many vegetable oils are long-chain hydrocarbons and contain reactive functionality (i.e., double bonds or hydroxyl groups) they may be easily processed into fatty acids. Hence, many greases use fatty acid soaps derived from vegetable oils (e.g., castor oil).

## 2.26.2 Deterioration of Lubricants

### 2.26.2.1 Deterioration by Combustion Products

Lubricating oils deteriorate in service in two primary ways: they become contaminated and they undergo physical and chemical changes due to oxidation.<sup>2</sup> In engines the common contaminants are airborne dust and wear products, unburnt fuel, fuel combustion products, and water. The oxidation products are mainly acidic materials and asphaltenes. Asphaltenes in association with fuel contaminants and water tend to form solids such as sludges and lacquers that can coat component parts and become entrained in the lubricant. The acidic materials resulting from oxidation of the lubricant oil are generally weak organic acids. However, contamination by fuel combustion products (i.e., oxides of sulfur and nitrogen) is the source of almost all strong-acid contamination in lubricants. Recent trends in fuel compositions have resulted in the amount of sulfur, particularly in diesel fuels for automotive use, being reduced considerably. However, heavy fuel oils and residual diesel fuels can contain several percent of sulfur by weight. This sulfur is oxidized to sulfur acids, and sulfuric acid condensate

may be encountered on the cooler surfaces. In petrol (gasoline) the sulfur content is now generally very small to negligible. Historically, halogen compounds added to gasoline as scavengers for lead-based anti-knock compounds could be oxidized to halogen acids; however, with the general elimination of lead in this role, this is no longer of significant concern.

Water, absorbed from the environment or as a product of combustion, exacerbates the problem of acids in oils as the presence of water both promotes corrosion and solvates any ions present, including hydrogen ions from combustion acids. For this reason, lubricant oils for internal combustion engines frequently contain additives to combat acidity. Generally however, provided the water content in lubricating oil remains below about 0.1%, few problems occur.

### 2.26.2.2 Oxidative Degradation

Apart from unusual and highly specialized materials (i.e., lubricants based on silicone chemistry or fully fluorinated hydrocarbons) lubricants, being hydrocarbon based, are relatively susceptible to deterioration by oxidation.<sup>3</sup> Oxidation, being a thermally activated process, will increase in rate with temperature although this will depend on the nature of the compound being oxidized. Thus, oils with a high aromatic content (LVI and some MVI oils) tend to oxidize to give sludge-forming compounds, although some naphthenic oils give organic acids. Paraffinic (long-chain) oils (HVI and some MVI oils) oxidize more slowly to give weak acids.<sup>4</sup> In a plentiful supply of oxygen, oxidation proceeds at a significant rate at temperatures above about 60–130°C depending on the composition of the lubricant. This oxidation is a complex process that typically involves the formation of organic peroxides as intermediates, which facilitate further hydrocarbon chain scission (breaking) or polymerization to form tars, sludges, and varnishes. Oxidation of hydrocarbons is catalyzed by the presence of transition metals with multiple oxidation states, such as copper, iron, and lead.

Oxidative degradation of hydrocarbons will, of course, lead eventually to the formation of carbon dioxide and water. Generally, however, lubricants form intermediate oxidation products, including aldehydes, ketones, and alcohols, with carboxylic acids as the common final oxidation products. Thus, the acidity of lubricating oils during use tends to increase as a function of time. Also, the intermediates, especially ketones and aldehydes, can polymerize, especially in the presence of strong acids from the

products of combustion (nitric and sulfuric). The presence of acidity is clearly corrosive to components and will form metal ion carboxylates (soaps) that are catalytic to oxidation. Thus, the oxidation of octane is accelerated from 5–10 times in the presence of 500 ppm iron octanoate<sup>3</sup> and excessive copper or iron will generally significantly enhance oxidation of lubricants at higher temperatures.<sup>5</sup> Lubricant (and fuel) additives may be formulated to control oxidation, corrosion, acidity, and radical formation in order to limit the degradation of the lubricant. However, such additives will themselves degrade (or be consumed) with time, hence the importance of regular changes of engine lubricants.<sup>6</sup>

### 2.26.2.3 Biodeterioration

Hydrocarbons provide a potential nutrient source of carbon for microorganisms and, consequently, lubricants and fuels are susceptible to biodeterioration by a range of fungal and microbial species.<sup>7</sup> Indeed, selection of specific microbial strains is of increasing interest as a mechanism of bioremediation of waste hydrocarbons. Lubricants are not normally susceptible to biodegradation unless they contain a significant separated water phase. However, the presence of 10–100 ppm water is sufficient to permit microbial growth on interfaces; thus, apparently water-free – (<0.1%) lubricants can contain significant microbial contamination. Lubricants can be particularly susceptible to biodeterioration since they contain essential elements for microbial activity (e.g., phosphorus, sulfur, nitrogen, etc.) in significant quantities. Engine and machinery lubricants that operate at a sufficiently high temperature in a closed environment will be essentially sterile. However, significant problems occur where lubricants are used at lower temperatures. Thus, metal-working lubricants (cutting fluids, etc.) that are left, for periods of time, open to the air at room temperature have increased susceptibility to microbial attack<sup>8</sup> unless a suitable biocide is present in the formulation.

## 2.26.3 Lubricant Additives

### 2.26.3.1 Types of Additive

The progressive development of engines and general machinery resulting in more arduous operating conditions, and particularly the use of longer oil-change periods, means that neither straight mineral oils nor compounded oils (mineral oils to which a proportion of an animal or vegetable oil has been added) are adequate for modern service requirements.

Despite the introduction of new, improved methods of refining, it has been necessary to enhance the performance of lubricants by the use of additives, either to reinforce existing qualities or to confer additional properties. Thus, almost all quality lubricants on sale today contain one or more additives. An enormous range of additives are available for use in lubricants, some produced by the oil companies and others provided by specialist manufacturers.<sup>9</sup> Additives are usually named after their particular function, but many additives are multifunctional. Thus, an antiwear additive may also protect a surface against corrosion. The main types of additive that can enhance the behavior of lubricants are listed in [Table 1](#).

As can be seen from [Table 1](#), many compounds are multipurpose and can act in a number of ways, some beneficial, some detrimental. The selection of additives thus involves a careful balance of properties for the required application.

### 2.26.3.2 Extreme Pressure Additives

Many additives, essential to the performance of the lubricant, provide no corrosion protection and some additives may become corrosive in certain circumstances. Thus, extreme pressure (EP) antiwear additives contain chemical groups which are designed to react chemically with metal surfaces when normal lubrication fails, forming easily sheared layers of metal oxides, sulfides, chlorides, or phosphates, thereby preventing catastrophic wear and seizure. Reaction between EP compounds and metal surfaces should only occur at local hot spots and the layers formed are extremely thin.<sup>10</sup> However, if the operating conditions are very severe these layers are continually generated and removed as they fulfill their antiwear function. A process of this nature is sometimes called ‘chemical’ wear, and if sliding surfaces operate continually under these conditions loss of metal from the rubbing surfaces can ultimately result in failure. Alternatively, all the EP additive may be used up (depleted) and then failure by seizure will occur. EP agents are intended to cater for the occasional overload condition and it must be emphasized that machinery should be designed so that it does not require the continual action of EP agents to function satisfactorily. Obviously, the selection of an EP additive requires great care; if it is too active, it may give rise to excessive metal removal (effectively corrosion) under normal operating conditions. Also, if a component is prone to ‘fatigue pitting’ (a form of contact fatigue in which fatigue cracks grow in such a way as

**Table 1** Lubricant oil additives that can enhance anticorrosive function

<i>Additive</i>	<i>Function</i>	<i>Chemical types</i>
Antioxidant	To increase oxidation resistance of lubricants by interfering with the reactions that give rise to acid and asphaltene (polymer) formation	Oil-soluble amine and phenol derivatives (<120°C), dialkyldithiophosphates and compounds listed below as metal deactivators (>120°C)
Metal deactivator	To form inactive protective films on metal surfaces which would otherwise catalyze oxidation and corrosion reactions	Trialkyl and triaryl phosphites, organic dihydroxyphosphines, some active sulfur compounds, diamines; for greases mercaptobenzothiazole and phosphites
Corrosion/rust inhibitors	To protect metal surfaces, particularly bearing surfaces, against corrosion/to eliminate rusting in the presence of moisture	Zinc dialkyldithiophosphates; esters and derivatives of dibasic acids (e.g., barium and calcium sulphonates)
Water repellents	To impart water-resistant properties, particularly in greases	Aliphatic amines, hydroxyl fatty acids and organosilicone polymers
Basic compounds	To neutralize acids	Barium and calcium salts of sulphonic acids and alkyl salicylic acid
Dispersants/detergents	To keep insoluble combustion and oxidation products in suspension and dispersed	Salts of phenolic derivatives, polymers containing barium, sulfur and phosphorus; calcium or barium salts of sulphonic acids
Antiwear/extreme pressure	To protect metal surfaces from binding together (seizure) by formation of a surface reaction product that is easily sheared under local high pressures and temperatures	Sulfur or phosphate esters/amines, halogenated compounds (the latter are decreasing in use)

to cause ‘chips’ of metal to detach from the surface) in service the presence of an overactive EP agent may result in corrosion fatigue.

### 2.26.3.3 Interactions Between Additives

Modern high-performance lubricants contain a number of additives, each with a particular, special function. Thus, a turbine lubricant may contain an oxidation inhibitor, a rust inhibitor, an EP agent, and an anti-foam compound. A high-grade diesel-engine lubricant may contain a viscosity improver, a dispersant, an antioxidant, a corrosion inhibitor, a basic compound, a pour-point depressant, and an antifoam compound. Sometimes, these additives may have undesirable side effects or interact adversely; in turbine oil, the rust inhibitor may act as an emulsifier, interfering with demulsification; in a diesel lubricant, the dispersant may promote oil oxidation. Frequently anticorrosion additives may not be able to exert their maximum effect because they are competing for sites on metal surfaces. The development of successful new lubricating oils requires skill and experience and always necessitates considerable laboratory and field testing in order to strike the right balance between the various additives.

### 2.26.3.4 Additives in Greases

All classes of additive mentioned earlier may be incorporated in the oil phase of greases and have similar function. However, with greases there is also the opportunity to employ oil-insoluble species that will partition to the emulsifying (soap) phase. The complete range of conventional water-soluble corrosion inhibitors, for example, nitrites and molybdates, can thus be easily incorporated into greases. However, care is required to avoid unwanted antagonistic interactions with other additives.

### 2.26.3.5 Sulfur-Containing Additives

Sulfur compounds occur naturally in most lubricants and many oil additives contain sulfur. In a properly formulated lubricant, these sulfur compounds should be inactive at ambient temperature. At elevated temperatures, they may decompose to give more active materials which can stain and corrode metals, particularly silver and copper. However, these same sulfur compounds have many beneficial qualities; this is why they are not removed completely in refining and why they are used as additives.

Thus, sulfur compounds in lubricants generally act as antioxidants, preventing acid and sludge formation. They can also adsorb or react to form thin films on metal surfaces protecting them from acid or peroxide attack. In addition, sulfur compounds are often used as EP agents. The oil chemist must try to strike a balance; the activity of the sulfur must be high enough for it to exert a beneficial effect and yet not so high as to stimulate corrosion.

All too frequently lubricants containing sulfur are exposed to more severe operating conditions than intended, and staining and corrosion may result. With traditional bearing materials, such as those containing silver and copper, significant corrosion can result, particularly where the sulfur-containing species have partially degraded. A more widespread problem is the corrosion of phosphor-bronze alloys (containing about 10% tin) particularly where temperatures can exceed 200°C. Two important metallurgical factors affecting the corrosion resistance of phosphor-bronze alloys are the amount of alloying element in solution in the copper-rich phase and the porosity of the alloy. For example, if the amount of tin in the solution can be increased by special casting techniques or heat treatments, the corrosion resistance is greatly increased. Similarly, zinc or silicon in solution also increases the resistance of copper to sulfur corrosion. If the alloy is porous the lubricant is drawn into the pores where it stagnates, and, at high temperatures, becomes very corrosive. Thus, as noted above, copper catalyzes oil oxidation with the consequent formation of corrosive sulfur compounds.

The most satisfactory solution to such problems is to employ corrosion-resistant bearing alloys. Traditional alloys with relatively high levels of tin and alloys of the gunmetal type, containing 2–4% zinc, have proved completely satisfactory. The substitution of zinc for phosphorus gives sounder castings and improves the corrosion resistance of the copper-rich matrix. More modern bearing materials such as thermally sprayed aluminum-copper-tin-(indium) have much improved resistance to such corrosion.<sup>11</sup>

## **2.26.4 Corrosion in Specific Lubricant Systems**

### **2.26.4.1 Internal Combustion Engine Lubricants**

Engine lubricants are exposed to severe operating conditions, being subjected to high temperatures, the products of combustion and a plentiful supply

of oxygen. Consequently, unless the oil is changed at appropriate intervals, strong mineral acids and weak organic acids may accumulate. In addition, droplets of water may be formed and these can contain strong mineral acids derived from the fuel combustion gases. These droplets sometimes give rise to emulsions which deposit in the colder portions of an engine, for example, on the rocker-box covers; ferrous surfaces are most affected by this condensed moisture. A special dynamic corrosion test has been developed to study corrosion in these two-phase (water-in-oil) systems.<sup>12</sup> Problems associated with the retention of water in engine lubricants are likely to become more acute as antipollution devices are fitted to engines. The harmful effects are best countered by antirust and basic additives, and in diesel engines burning high-sulfur fuels, for example, marine diesel engines, very high levels of lubricant basicity are required.

Cast or sintered copper-lead or lead-bronze alloys are still widely used for engine bearings. The lead phase in such bearings is readily attacked by weak organic acids and almost all the lead can be leached out unless preventive measures are employed. However, the lead may be protected by an overlay of a lead-tin or lead-indium alloy.<sup>13</sup> About 3% tin or 5% indium in lead will render the lead resistant to attack by oil-oxidation acids. One reason why leaded bearings are protected by an overlay, and not by incorporating the protective alloying elements in the underlying lead, is that both tin and indium dissolve preferentially in copper.<sup>14</sup> In a cast or sintered bearing, therefore, any tin or indium will be found in solution in the copper-rich phase, leaving the lead-rich phase susceptible to attack. Aluminum-copper-tin alloys, which are increasingly used in modern automotive applications, are significantly more resistant to corrosion than conventional copper and lead-based alloys.

### **2.26.4.2 Corrosive Wear**

Modern efficient engines that require extended service intervals and minimum maintenance, and that are able to accept a wide range of fuels whilst meeting strict exhaust emission standards, present special lubrication problems. In particular it is essential that the lubricant can prevent corrosion from fuel combustion products retained in the engine. Corrosive wear can be reduced or prevented by alkaline additives that can neutralize the acids responsible, by additives that prevent the acids reaching metal surfaces and by antirust additives that are adsorbed on metal surfaces and prevent the access

of water and oxygen.<sup>15</sup> Often all three additive types will be used in association although their relative concentrations will depend on the nature of the corrosive agents. In spark-ignition engines the use of nonconventional fuels such as compressed natural gas (methane), liquefied petroleum gas (propane and butane), methanol, ethanol and lead-free gasoline can give specific corrosion problems.<sup>16</sup> Broadly, organic acids of shorter chain length and greater acidity (lower  $pK_a$ ) are generated from such fuels compared with normal gasoline, so higher additive levels are required.

Diesel-fuel sulfur levels can range from about 0.2% to 5.0%. The higher levels only occur in low- and medium-speed engines operating on residual fuels, but because of the high combustion pressures, sulfuric acid condensate forms at temperatures up to 200°C. On cross-head engines, which have independent cylinder lubrication systems the neutralizing power of the fresh oil depends on both oil feed rate and alkalinity.<sup>17</sup> The alkalinity of the lubricant is measured as the total base number (TBN) and lubricants with a TBN exceeding 100 are now available. This means that the lubricant has an acid neutralizing capacity equivalent to a 10% aqueous solution of KOH in oil-soluble form. Experience shows that when fuels with sulfur contents of 2.0% or more are used, the TBN of oils draining from the cylinders should not fall below 10 if excessive wear rates are to be avoided. However, the use of highly alkaline cylinder oils with low sulfur fuels is not recommended; not only is it needlessly expensive, it can also give rise to high wear rates.<sup>15,17</sup> In splash-lubricated piston engines running on high sulfur fuels, the copious quantities of oil splashed up from the crank case provide a greater reservoir of alkalinity and an initial TBN of 25–30 is generally adequate. Nevertheless, the TBN of the oil should not fall below about 3 times the sulfur content of the fuel.

#### 2.26.4.3 Steam Turbine Lubricants

Lubricants in steam turbines are not exposed to such arduous conditions as those in engines. Thus, their main requirement is for high oxidation stability. However, they may be exposed to aqueous condensate or, in the case of marine installations, to sea water contamination, so they have to be able to separate from water easily and to form a rust-preventing film on ferrous surfaces, and it is usual to employ rust inhibitors. The problem of tin oxide formation on white-metal bearings is associated with the presence of water condensate in lubricants and can be

overcome by keeping the lubricant dry or by the incorporation of appropriate inhibitors.<sup>18</sup>

#### 2.26.4.4 Gear Lubricants

In addition to the usual oxidation and corrosion inhibitors, lubricants for heavily loaded gears almost always contain EP additives containing sulfur, chlorine, or phosphorus. In order to function, these additives must react locally with the metal surfaces, and yet the extent of the reaction should not be such that it could be described as corrosive, or promote fatigue pitting. These EP additives may be quite safe with ferrous surfaces, but may cause severe corrosion on copper alloys, for example, on bronze worm wheels, if for any reason excessive temperatures arise. Some turbine lubricants have to lubricate the turbine gears as well as the turbine; in these circumstances, any EP additives employed should not be corrosive in the presence of moisture.

#### 2.26.4.5 Cavitation and Erosion

Cavitation and consequent erosion are an insidious cause of failure in plain bearings and hydraulic systems.<sup>19</sup> Vapor cavities form locally in reduced pressure areas of the lubricating fluid and then collapse rapidly in higher pressure regions. The shock waves generated by the vapor collapse can result in mechanical (impact) damage on surfaces. Common causes of cavitation are pressure fluctuations associated with the flow of the liquid and the vibration of a surface in contact with it. Unlike other kinds of damage, vapor cavitation is generally encountered on the unloaded areas of bearings. When the damage is due solely to cavitation, the damaged surfaces are rough: when foreign particles are present they are smooth (cavitation–erosion). Vapor cavitation can remove protective films, such as oxides, from metals and so initiate corrosion. In addition, the very high local pressures and temperatures associated with the final stage of cavity collapse can induce chemical reactions that would not normally occur. Thus certain additives are damaged by cavitation and their decomposition products can be corrosive.

#### 2.26.4.6 Metal-Working Lubricants

Metal-working lubricants can be divided into two categories: metal cutting lubricants and metal forming lubricants.<sup>20</sup> Three types of cutting fluids are widely

used: soluble oils, water base fluids and straight cutting oils. Soluble oils are low-viscosity mineral oils (containing emulsifying agents) that, when added to water, form stable oil-in-water emulsions. Their main function is to cool the workpiece rather than to lubricate, but they should contain rust inhibitors to prevent corrosion of both the workpiece and the machine. Water base fluids contain no oil and employ the normal corrosion inhibitors used in coolants, for example, sodium nitrite, sodium benzoate, and triethanolamine phosphate. Straight cutting oils are used in severe operations where good lubrication is essential, and generally contain EP additives that should be carefully selected so that they do not corrode (stain) the workpiece or the machine tool. For example, very active sulfur compounds should not be employed with copper alloys. Chlorinated additives should be stable in moist air to avoid the risk of hydrochloric acid formation.

Metal-forming lubricants include formulations for rolling, drawing, extruding and forging. A vast range of compounds including fatty oils and compounded oils are used in these operations, and a major requirement is that they should not stain the workpiece during the forming operation or during subsequent annealing or in storage. Consequently, all oils and additives employed should be completely volatile, in addition to affording protection against rusting.

#### **2.26.4.7 Water Base Lubricants**

In some applications, for example, mining machinery, nonflammable lubricants are specified and water base or water-containing fluids are used. Standard corrosion inhibitors are used to combat corrosion but even a small amount of water in a mineral oil lubricant can adversely affect the fatigue life of components such as rolling bearings and gears.<sup>21</sup> Worthwhile improvements in fatigue life can be achieved by using additives of a completely different nature and by special heat-treatment techniques.<sup>22</sup>

#### **2.26.4.8 Lubricants for Other Applications**

Specially formulated lubricants are required for steam engines, compressors and exhausters, refrigerators, hydraulic equipment, textile machinery, transformers and switchgear, nuclear power plants, and many other diverse applications. Most of these lubricants will contain a carefully balanced set of additives, including some to prevent corrosion either directly by protecting the metal surface, or indirectly by

preventing deterioration of the lubricant and combating the action of contaminants. When corrosion is encountered with a specialized lubricant, the cause is not likely to be any weakness on the part of the lubricant; it is probable that the lubricant is being exposed to extreme operating conditions, far more than those for which it was designed.

### **2.26.5 Monitoring and Testing**

#### **2.26.5.1 Oil Condition Monitoring**

Historically, regular changes in lubricant ensured that they remained in optimum condition. However, lubricants are expensive and users have no wish to change them until necessary. Thus, much greater attention is now given to intermittent or continuous (online) monitoring of the condition of the oil and associated machinery.<sup>23</sup> Oil condition monitoring is often extended to include techniques that give advance warning of the deterioration or impending breakdown of the machinery, whether or not this is associated with loss of performance of the lubricant. Conventional condition monitoring collects particulate debris, for example, by magnetic filtration, and subjects these to *ex situ* analysis, typically for elemental components. Such methods include ferrography and spectrographic oil analysis SOA.<sup>24</sup> More recent techniques have been developed for online (*in situ*) use and these include particle counting, infrared analysis,<sup>25</sup> electrical methods<sup>26</sup> as well as online viscosity<sup>27</sup> measurement.

#### **2.26.5.2 Testing**

Methods for the testing and analysis of lubricants are the subject of many Company, National, and International Standards.<sup>28</sup> Typical tests for used diesel engine oils include viscosity, fuel dilution, flash point, water content, ash level, insoluble species, and neutralization value. Neutralization value is a measure of the acidity (total acid number, TAN), or alkalinity (total base number, TBN) of the oil. Laboratory examination of used oil samples and reporting results takes time and the simpler tests can be used in the field. Extensive tests for the performance (oxidation resistance) as well as for the corrosivity of oils and greases also exist and lie within the BS2000 series (now generally superseded) and the ASTM 'D' series. Thus, the most commonly known test for corrosivity of lubricants is the copper strip corrosion test specified in

BS 2000-112:2005; "Methods of test for petroleum and its products: Determination of corrosiveness to copper of lubricating grease (copper strip method)," which is broadly equivalent to ASTM D 130.

### 2.26.5.3 Health and Safety

The solvent action of mineral oil base stocks can cause skin problems and prolonged exposure has been found to be carcinogenic.<sup>29</sup> Thus, the use of additives that might be in any way harmful to health, for example orthotricresyl phosphate (antiwear) and sodium mercaptobenzothiazole (anticorrosion), is discouraged and discontinued where skin contact is likely. The presence of fungi and bacteria in water base or water-contaminated lubricants such as machining fluids and marine diesel crankcase lubricants may promote corrosion and are potentially of concern to health.<sup>30</sup> More broadly, increasing environmental concerns in recent years is driving research on environmentally friendly disposal of used lubricants and substitution of nonbiodegradable mineral oils with fully biodegradable oils that are often plant derived.<sup>31</sup>

### Glossary

**Biocompatibility** The extent to which an implanted material elicits an immune response in a host.

**Carcinogen** Cancer causing.

**Cardiac** Related to the function of the heart.

**Cytotoxicity** Toxic towards cells.

**Extracellular** The space outside the plasma membranes of cells and occupied by fluid; literally means outside the cell as opposed to intracellular which is inside the cell.

**Hematoma** A collection of blood, usually partially clotted, that results from the breakage of veins or blood vessels.

**Inflammatory response** Part of the human body's initial response to injury or infection.

**In vitro** Experiments conducted outside the body; literally means in-glass.

**In vivo** Data collected from materials implanted within a live subject, human or animal.

**Orthodontic** An area of dentistry concerned with treatment of the inability to bite correctly, due to the misalignment of teeth, irregular tooth growth or disproportionate relationship between the upper and lower jaws.

**Oral lesions** Abnormal tissue in or around the mouth, usually caused by disease or trauma.

**Oral mucosa** Mucous membranes of the mouth.

**Osteoporosis** Thin or porous bones caused by lack of calcium or stress shielding by load-bearing implants.

**Prosthesis** An artificial device that replaces a missing body part.

**Pathological changes** The human body's initial response to injury or infection.

**Pulmonary** Related to the function of the lungs.

**Serum** Blood plasma from which clotting factors have been removed.

**Shape-memory alloy** A material that, after it has been deformed, regains its original geometry by heating, due to temperature-dependent martensitic phase transformation.

**Sherman plates** Metal plates used to hold fractured bones in place to allow them to heal; typically the plate is screwed to the bone.

## Abbreviations

**ASTM** American Society for Testing and Materials

**FCC** Face Centered Cubic

**ISO** International Standards Organization

**L** Low carbon

**PREN** Pitting resistance equivalent number  

$$= \%Cr + (3.3\% \times Mo) + (16 \times \%N)$$

**SCC** Stress corrosion cracking

**SHE** Standard hydrogen electrode

**VM** Vacuum melted

## 2.27.1 Introduction

Corrosion is of concern to the biomedical industry for two reasons. The first is common to all industries, being ‘how will a device’s lifetime/performance be impacted by corrosion?’ However, the second concern is specific to the biomedical industry, being ‘will the metallic ions that leach out of the device build up to levels sufficient to harm the patient, for example, by causing tumors to develop?’ There is little known about what represents longterm safe limits for metallic ion concentrations in the body, and therefore, these could well be exceeded at corrosion rates that are insignificant with respect to the physical performance of the implant. Corrosion problems in dental applications are more common, mainly due to the high acidity and chloride contents of many foodstuffs. Fortunately, fixtures in the oral cavity are readily accessible for repair or replacement, but the toxicity of the metals leaching out is a major concern.

In most industries, corrosion is typically controlled by either coatings or altering the local environment. Unfortunately, until recently, coatings were of limited use for protecting surgical implants, since many of these (especially orthopedic devices) are

subjected to wearing and abrasion processes. Likewise, the environment within the human body is essentially fixed, and therefore, it is not possible to lower the temperature or raise the pH. As a result, the only available method of reducing corrosion rates within the human body has been to fabricate the biomedical devices from a corrosion-resistant material. Nevertheless, since the late 1970s, this approach has been extremely successful, at least with respect to extending the lifetime of biomedical devices, thanks to the development of a range of corrosion-resistant alloys that have reduced the number of failures to extremely low levels. Besides, many of the few corrosion failures that still occur can be traced either to poor quality control or to an unexpected and unusually aggressive local environment around the implant, due to pathological changes in the surrounding tissue as this reacts to the surgical procedure. The remaining early failures of surgical implants are due to either fatigue or fretting, which may or may not be accelerated by corrosion.

Nevertheless, the lack of consensus over what represents safe levels for metallic ion concentrations within the body, or even which metals are toxic, means that the concerns about extended exposure to even very low levels of corrosion products resulting in medical complications remain. Furthermore, average life expectancies are increasing and the average age of patients receiving implants is decreasing. Ironically, this is both in part due to the modern popularity of physical sports, which place a large strain on joints, and therefore, the required performance lifetime of devices, and with it, the likelihood of both the corrosion-related failures and health problems instigated by elevated metallic levels is increasing. Additionally, a number of advanced materials, such as shape-memory alloys, are being introduced into the biomedical industry often with very little prior thought given to corrosion protection.

## 2.27.2 Historical Development

The earliest use of metallic materials in dental applications was over 4000 years ago in ancient Egypt; although initially for aesthetic purposes, by about 700 BC, this had developed to the level of using gold bridgeworks to secure false teeth formed out of ivory and bone. However, the modern era of using metallic surgical implants to fix damaged bones only began at the beginning of the twentieth century. Of the metals and alloys available at that time, vanadium

steel, developed in 1912, offered the best combination of corrosion resistance and mechanical strength. Although this alloy had poor tissue compatibility, it was not until the 1930s that austenitic stainless steels became sufficiently available as a viable alternative, first with compositions similar to that of grade 304 and later with molybdenum additions, that is, evolving towards grade 316L, which was endorsed by the American College of Surgeons in 1946.<sup>1</sup> In 1981, a 22Cr13Ni5Mo stainless steel was introduced for hip implants, but this was rapidly superseded by the introduction of high-nitrogen austenitic stainless steel, which offered the same corrosion resistance but without the need for a high-nickel content to maintain the FCC structure, dramatically reducing costs. In response to fears of nickel toxicity, the beginning of this millennium saw the introduction of nickel-free or low-nickel austenitic stainless steels implants, such as the nitrogen-strengthened 23Mn21Cr1Mo (ASTM F2229-02).

Cobalt–chromium–molybdenum alloys were first used in dentistry in the late 1920s and then for surgical implants in the late 1930s. The high corrosion resistance and apparent good biocompatibility made these alloys a favored material for orthopedic devices, but during the 1950s, the better strength-to-weight ratio of titanium meant that it started to increase in popularity; CoCrMo alloys remained the preferred choice in the United States up to the late 1960s. In 1974, the Ti6Al4V alloy,

which has a much higher ultimate tensile strength than the commercial purity titanium, was introduced for trauma implants, and by the end of that decade, it had become the material of choice in orthopedic surgery, although CoCrMo alloys were still regularly used.

The late 1980s and 1990s saw the beginning of the introduction of advanced materials for biomedical applications, including rare earth magnets and NiTi shape-memory alloys. In the present decade, zirconium alloy joint prostheses were introduced and important advances have been made in the application of wear-resistant titanium nitride coatings.<sup>1</sup> Undoubtedly, the nature of surgical and dental implant materials will continue to evolve in the coming decades.

### 2.27.3 Health Effects Related to Corrosion in Body Fluids

There is no doubt that surgical implants do raise the level of metallic elements in the body, as illustrated by the data displayed in Table 1.<sup>2–4</sup> However, the form of the metal released into the body is often uncharacterized, for example, particulate matter or soluble ions, with the role of serum protein binding being virtually unknown. Furthermore, there is still no agreement over what constitutes safe levels for metals within human body fluids and tissues. Although cobalt,

**Table 1** Approximate concentrations of metals in the human body with and without a total-joint replacement implant<sup>2–4</sup>

		<i>Metal ion concentrations: body fluids (μM); tissues (ppm)</i>						
		<i>Co</i>	<i>Cr</i>	<i>Mo</i>	<i>Ni</i>	<i>Ti</i>	<i>Al</i>	<i>V</i>

Source: Hallab, N. J.; Jacobs, J. J.; Gilbert, J. L. In Joint Replacement and Bone Resorption; Shanbhag, A., Rubash, H. E., Jacobs, J. J., Eds.; Taylor & Francis: New York, 2006; pp 211–254.

chromium, and nickel are essential trace elements, in excess, all these lead to carcinogenesis as well as other ailments;<sup>2</sup> likewise, vanadium leads to cardiac dysfunction and hypotension,<sup>2</sup> while iron has been linked with Parkinson's disease.<sup>5</sup> Excess aluminum can cause anaemia,<sup>2</sup> but claims that it causes Alzheimer's disease have been proved to be completely unfounded.<sup>6</sup> Titanium is a nonessential element, which is usually considered inert, but pulmonary disease has been reported in titanium production workers as well as in rats exposed to TiO<sub>2</sub> dust.<sup>2</sup>

The potential to cause cancer is obviously a major concern with metallic implants. Memoli *et al.*<sup>7</sup> reported a slight increase in sarcoma cancers in rats when implanted with devices with high Cr, Co, or Ni contents, and a significant number of implant site tumors have been reported in cats and dogs with stainless steel implants, but fortunately to date, malignant tumors associated with implants in humans are rare.<sup>8</sup> Nevertheless, the number of reported cases is increasing and is likely to continue to do so as the patient age decreases and the life-expectancy increases.<sup>9</sup>

Health concerns with orthodontic devices are also mainly associated with metal release, particularly nickel from stainless steels and the NiTi shape-memory alloy.<sup>10</sup> With respect to amalgams, apart from the release of toxic mercury, the main concern is the development of lesions of the oral mucosa that can lead to leukoplakia, lichen planus, and oral cancers. Early reports linked these lesions to the potential associated with galvanic cells that can exist between amalgams and precious metal restoration, and hence these have been termed galvanic lesions.<sup>11,12</sup> However, galvanic cells appear to be commonplace among healthy populations; Phillips *et al.*<sup>13</sup> did not find any evidence of leukoplakia in rats that were subjected to galvanic currents.<sup>14</sup> More recent studies have found that the lesions are usually caused by contact hypersensitivity to mercury<sup>15</sup>; the oral mucosa may be either in direct contact with an amalgam or contain some mercury deposits resulting from amalgam corrosion.<sup>16</sup> Clinical signs of amalgam corrosion have been reported to be significantly more frequent in patients suffering from oral lichen planus than in controlled groups, and of course, any galvanic cells between amalgams and precious metals would accelerate the corrosion and thus exacerbate the problem.<sup>17</sup> Nevertheless, lesions of the oral mucosa caused by amalgam restorations are rare and can usually be solved by replacement of the amalgam.<sup>15</sup>

## 2.27.4 Environments Encountered in Biomedical Applications

Upon detecting the presence of a foreign entity, the body will produce enzymes and attempt to ingest the foreign object. If the foreign object is too large to be ingested, such as a surgical implant, the body will isolate and encapsulate the object in a fibrous tissue membrane. As such, the implant remains continuously exposed to extracellular tissue fluid. Although the actual compositions of body fluids are complicated, in terms of corrosiveness, the most important characteristics are the chloride, dissolved oxygen, and pH levels. The biological components in body fluids, for example, phosphates, cholesterol, and phospholipids, are usually considered either to play no role in the corrosion process or to exist at insignificant levels. Figure 1(a) shows the typical environmental conditions expected within a range of different body fluids, superimposed on the Pourbaix diagram for chromium in the presence of chloride ions.<sup>18,19</sup> From this diagram, it can be predicted that stainless steels and cobalt–chromium–molybdenum alloys are likely to suffer corrosion in many of the environments found within the body, but titanium would be in the passive state for virtually all physiological solutions (Figure 1(b)). Fortunately, the body fluid most likely to be encountered by an implant is blood, which contains ~0.9% NaCl and under normal conditions is at pH 7.4, with a redox potential in the vicinity of 0.0 V versus standard hydrogen electrode (SHE) and body temperature of ~37 °C. Under these conditions, many stainless steels and cobalt–chromium–molybdenum alloys can be expected to be in the passive state.

A review by Solar<sup>20</sup> in 1979 concluded that inorganic solutions based on 0.9% NaCl were satisfactory substitutes for human body fluids when studying the behavior of passive metals. As a result, the majority of *in vitro* corrosion experiments have been conducted in either 0.9% NaCl or standard isotonic solutions, such as SBF-K9, Ringer's, or Hank's solution, in which additions of bicarbonate and calcium chloride tend to be the main difference to a simple NaCl solution. Dissolved oxygen levels in blood are lower than in saline solutions exposed to air atmospheres, by factors of about 2 and 6 for arterial blood and for venal blood, respectively. Conversely, bicarbonate levels are about 20 times higher in blood than in saline solutions (Table 2).<sup>21–23</sup> Usually, no attempt is made to lower the dissolved oxygen content of the isotonic NaCl solutions to that of the venal blood, which may

**Figure 1** Representative environmental conditions for various body fluids superimposed on Pourbaix diagrams for (a) chromium in solutions containing chloride and (b) titanium. The shaded zones represent the conditions for physiological solutions as suggested by Schenk.<sup>19</sup> Adapted from Blackwood, D.J.; Seah, K.H.W.; Teoh, S.H. In *Engineering Materials for Biomedical Applications*; Teoh, S.H., Ed.; World Scientific: Singapore, 2004; pp 3.1–3.56, with permission from World Scientific.

explain some of the minor differences between the *in vitro* and *in vivo* corrosion behaviors of surgical implant materials.<sup>22,24</sup> In addition, the minor components in blood, which are usually ignored in *in vitro* studies, have occasionally been blamed for accelerated

**Table 2** Comparison of oxygen and carbon dioxide levels in real and simulated human body fluids.<sup>21–23</sup>

	$P_{O_2}$ (mmHg)	$P_{CO_2}$ (mmHg)	$HCO_3^-$ (mM)

*in vivo* corrosion rates, for example, it has been reported that proteins can lower the pitting potential of 304L stainless steel.<sup>25</sup> Overall, it appears that typical body fluids are slightly less aggressive than is seawater, indeed Zitter<sup>26</sup> recommends that if a stainless steel is to be used to fabricate a biomedical device, it should have a pitting resistance equivalent number (PREN) not less than 26, somewhat below the value of 40 usually required for stagnant seawater.

Finally, it needs to be understood that the surgical operation plus the presence of the implant itself may cause the surrounding tissue to undergo severe pathological changes that can result in the development of a more corrosive environment. For example, Laing<sup>27</sup> reported that the buildup of hematomas, a condition that could last several weeks, can force the pH in the vicinity of a freshly inserted surgical implant down to as low as pH 4.0. Likewise, the initial stages of the inflammatory response can lead to the generation of hydrogen peroxide and elevated protein levels, both of which may favor the initiation of pitting and crevice corrosion.<sup>21,28,29</sup> Furthermore, the degree to which pathological changes occur depends not only on the biological activity of any released corrosion products, but also on the size and shape of the implant, which means that the extent of the pathological changes will vary across the surface of an implant. This could lead to the development of electrochemical cells and the potential gradients necessary to drive localized corrosion.

The environment within the oral cavity is not well defined. There are a number of recipes for artificial saliva, of which the most common is that of Fusayama<sup>30</sup> (NaCl, 0.400 g dm<sup>-3</sup>; KCl, 0.400 g dm<sup>-3</sup>; CaCl<sub>2</sub>·H<sub>2</sub>O, 0.795 g dm<sup>-3</sup>; NaH<sub>2</sub>PO<sub>4</sub>·H<sub>2</sub>O, 0.69 g dm<sup>-3</sup>; Na<sub>2</sub>S·9H<sub>2</sub>O, 0.005 g dm<sup>-3</sup>; pH 5.5), which may be acidified with citric acid to pH 4.0. However, in reality, the makeup of human saliva varies considerably between individuals, especially in the sulfide

content, which can cause tarnishing of both silver- and gold-based amalgams. In any case, many food-stuffs are acidic with high-chloride levels, and are thus far more corrosive than saliva. Moreover, oral hygiene has a strong affect on the corrosiveness of the oral environment. Many dental products also contain fluoride, some of the specialist varnishes used by dentists being over 2 wt% fluoride, which can cause corrosion even in commercial purity titanium.<sup>31</sup> An example of the problem of defining the environment for the oral cavity is illustrated in the work of Schiff *et al.*,<sup>32</sup> who investigated the corrosion performance of different orthodontic wires. All showed excellent resistance in artificial saliva, but in monofluorophosphate-containing mouthwashes, NiTi-based alloys were found to suffer strong corrosion, while TiNb alloys and TiMo-based alloys gave satisfactory performance. However, when a mouthwash containing stannous fluoride was used, the NiTi alloys outperformed the other two alloys, the TiMo alloys corroding badly.

### 2.27.5 Metals and Alloys Used in Biomedical Applications

In addition to an alloy's mechanical and corrosion resistance properties, its surface finish is also an important aspect for biomedical devices. The type of surface finish required on an implant is very much dependent on its final use. For example, on the one hand, for prostheses implants usually a rough surface is desirable, as this promotes attachment to the surrounding bone or cement. On the other hand, implants that come into contact with the blood stream, such as vials or reservoirs used to hold the chemicals required in chemotherapy, need to have smooth surfaces to prevent provoking thrombus or crystal formation of the applied chemotherapeutics. As a result, the compositions, mechanical properties, and surface finish of the major types of metals and alloys available are governed by a range of international and national standards, most notably, the various parts of ISO 5832.

#### 2.27.5.1 Titanium and Titanium Alloys

Titanium has excellent corrosion resistance to most environments likely to be found *in vivo*, with the possible exception of acid anoxic regions (e.g., gastric fluids) where the protective passive oxide may not form. The ability of the passive oxide film to provide corrosion

protection can be improved by anodizing; note that earlier concerns that anodizing may reduce titanium's resistance to stress corrosion cracking (SCC) and corrosion fatigue appear to be unfounded.<sup>33</sup>

Titanium alloys have even better strength-to-weight ratios than does pure titanium, but not quite as high a resistance to pitting corrosion as the parent metal has, and problems can be encountered if the local redox potential is high and the pH low. Theoretically, these conditions could exist during the initial stages of the inflammatory response following surgery, when both a reduction in pH and hydrogen peroxide production can occur, but the author is not aware of any such clinical cases.<sup>21,27–29</sup> Overall, titanium alloys have better corrosion resistance than do cobalt–chromium–molybdenum alloys and stainless steels.

In the previous decade, concerns about the cytotoxicity of vanadium have led to the development of a number of new alloys as potential replacements for the dual phase ( $\alpha + \beta$  phases) Ti6Al4V alloy; there have been reports of elevated metal levels in soft tissues and bones surrounding implants fabricated from this alloy.<sup>34</sup> Many of the potential replacements are  $\beta$  stabilized, which allows a lower elastic modulus and thus should aid bone growth, but at the cost of lower wear and fatigue resistances. However, two replacement alloys, Ti15Mo5Zr3Al and Ti6Al2Nb1Ta0.8Mo, have already been used in hip prostheses in cemented and noncemented applications, respectively, with apparently excellent clinical results.<sup>35</sup>

Despite their excellent corrosion resistance and biocompatibility, titanium and its alloys are still not the perfect biomedical materials, as their poor shear strength makes them unsuitable for screws and other forms of fastener devices. This can lead to fixation problems if galvanic corrosion is to be avoided between the titanium alloys and attaching screws. In addition, titanium alloys also have a high coefficient of friction, which means that wear particles may form if rubbing against bone or another implant surface occurs; the latter case has led to failures due to fretting corrosion, in which the passive oxide film is worn away.<sup>36</sup> The poor fretting resistance of the Ti6Al4V alloy represents its most serious drawback for use in load-bearing prosthesis, and therefore, considerable effort has been made to find possible solutions.<sup>37–40</sup> Encouraging results have been reported for both anodizing and titanium nitride coatings.<sup>37,41</sup> Anodization has the advantages of low cost and ease of operation, while the nitride-coated Ti6Al4V has the better fretting resistance<sup>38</sup>; both techniques have demonstrated

biocompatibility.<sup>37,42</sup> Recently, a zirconium alloy containing 2.5% niobium has been introduced for joint prosthesis. A thick oxide layer formed on the Zr2.5Nb by heating to 535°C gives it a far superior wear resistance to that of titanium alloys.<sup>43</sup> Zr alloys have similar corrosion resistance properties to titanium, but are difficult to machine as they show pyrotechnic tendencies.

### 2.27.5.2 Cobalt–Chromium–Molybdenum Alloys

The main alloys used are based on either CoCrMo alloy, which has been used extensively in dentistry and more recently for artificial joints, or CoCrNiMo, which has a very high ultimate tensile strength and thus is used for making the stems of prostheses for heavily loaded joints. Molybdenum is added to improve the mechanical properties by decreasing the grain size, rather than to improve the corrosion resistance. These alloys have excellent resistance to most forms of corrosion, including crevice corrosion and corrosion fatigue, but fretting corrosion can cause failures. The nickel-containing alloys have the better corrosion resistance, and ASTM F1058 (40Co20Cr15Ni7Mo) has a long track record as a permanent implant alloy.<sup>44</sup> However, concerns about the release of toxic Ni<sup>2+</sup> ions have resulted in the CoCrMo alloy, ASTM F75 being the dominant cobalt–chromium–molybdenum alloy in use today. A final concern with using CoCrMo alloys is the potential release of chromate, a known carcinogen, into the body. This worry also applies to stainless steels, since these too contain chromium, although at lower levels.

### 2.27.5.3 Stainless Steels

Early attempts to use 12% Cr Sherman plates with type 304 stainless steel screws led to predictable galvanic corrosion problems; nonetheless, some of these plates remained in patients for over 30 years, only being removed when tumors (nonmalignant) develop over the corroding implants.<sup>45</sup> The galvanic corrosion problem was solved by using an all type 304 stainless steel construction, but this did not prevent problems associated with pitting and crevice corrosion. Nevertheless, small type 304 stainless steel Sherman plates have been removed from patients after ~30 years of service without any sign of corrosion; possibly the low oxygen content of body fluids prevented the pitting potential from being exceeded.<sup>21</sup> In contrast, a

number of cases of larger type 304 stainless steel implants developing localized corrosion problems shortly after implantation have been reported.<sup>46</sup> These apparently contradictory results bear testament to the importance of the pathological changes that accompany the healing process in the first few weeks after surgery, and the extent of the healing process can be expected to be dependent on the size of the implant.<sup>21</sup>

The development of the molybdenum-containing type 316L stainless steel led to a significant decrease in the number of failures related to localized corrosion. However, from a review of failures during the years 1980–1989, Zitter<sup>26</sup> suggested that a PREN greater than 26 was required to prevent *in vivo* pitting corrosion, which is slightly above the PREN of most type 316L stainless steels produced, making this grade more suitable for temporary implant devices. The PREN value can be pushed above the recommended threshold of 26 by the addition of nitrogen, which also has the advantage of increasing the ultimate tensile strength of the material, but at the expense of a lower elongation at fracture. During the last two decades, the importance of sulfide and phosphide inclusions in pit initiation processes has been recognized and this has led to the development of type 316LVM stainless steel, in which the nonmetallic inclusion content is reduced by vacuum melting. The composition of the 316LVM grade is usually slightly above the normal 316 specification, typically being 18Cr14Ni3Mo, such that its PREN value of ~28 is above Zitter's threshold limit. The recently developed low-nickel stainless steels such as 23Mn21Cr1Mo (ASTM F2229-02) are nitrogen strengthened, which can also push their PREN beyond 26.

The superior mechanical and formability properties of stainless steels over titanium alloys are a great advantage in orthodontic applications. However, the consumption of acidic food and beverages means that there is a much greater risk of localized corrosion in the oral cavity than inside the body. To counter this threat, ultraclean high-nitrogen austenitic stainless steels have been developed, for example, 21Cr10Ni3Mo0.3Nb0.4N.<sup>47</sup>

### 2.27.5.4 Nickel–Titanium Alloy

NiTi is a shape-memory alloy with super-elasticity, a property that is of interest in both surgical and dental applications. Mantovani<sup>48</sup> reviewed the possible uses of NiTi in medical appliances, typical applications

including dental braces, medical staples, and nails. The most likely form of corrosion on NiTi is pitting; its resistance to pitting in body fluids appears to be similar to that of 316L stainless steel type.<sup>49</sup> However, NiTi fares worse than stainless steel orthodontic wires in acidified artificial saliva.<sup>50</sup> Given that there is some evidence that nickel initiates cancer, the high nickel content of NiTi is a matter of concern.<sup>2</sup> To date, studies indicate that the amount of nickel released into the body from the corrosion of NiTi depends on the local environment and the tests in artificial saliva showed similar Ni release rates to 316L stainless steel,<sup>51</sup> while in simulated body fluids, the NiTi released three times as much nickel as in artificial saliva.<sup>52</sup> Rather alarmingly, Heintz *et al.*<sup>53</sup> found that when fibroblast cells adhere to the NiTi alloy, they damage the oxide film, leading to rapid localized corrosion and that this has caused failures in stent wires of explanted endovascular grafts. Hashimoto and Morita<sup>54</sup> have also reported significantly higher nickel ion release rates in the presence of living fibroblast cells. The mechanism by which this accelerated corrosion occurs is not yet known, possibly the attached fibroblasts lead to the development of occluded electrochemical cells. Nevertheless, the biocompatibility of NiTi, as determined in short-term *in vivo* tests on guinea pigs, was reported to be comparable with type 316LVM stainless steel.<sup>55</sup> This view appears to be supported by the largely favorable surgical clinical evidence available to date, including excellent biocompatibility in tendon tissue, minimal corrosion on retrieved implants, and nickel concentrations in the major organs at levels similar to those for stainless steel devices.<sup>56</sup> However, the concerns about potential Ni release and its poor performance in dental applications have led to a number of efforts aimed at improving the NiTi alloys' resistance to pitting corrosion, the most promising techniques being diamond-like carbon coatings and nitriding.<sup>57–59</sup> Recently, a new nickel-free shape-memory alloy has been developed, Ti18Nb4Sn, with a corrosion resistance in simulated body fluids apparently comparable with that of commercial titanium.<sup>60</sup> Once acceptable biocompatibility of this alloy has been demonstrated, there is a good chance of it eventually replacing NiTi, at least in orthodontics.

### 2.27.5.5 Porous Materials and Metallic Foams

As demonstrated earlier, titanium alloys and CoCrMo alloys have excellent corrosion characteristics for the

construction of surgical implants. However, the elastic moduli of these solid metallic alloys are much higher than those of human bone, which means that stresses are not transferred to the surrounding bone effectively, leading to irregular bone growth and osteoporosis. One possible solution to this problem is to use porous implant materials that have lower elastic moduli closer to those of human bone. Such porous materials not only have the advantage of a more suitable elastic modulus, but also open up the possibility of allowing bone growth into the implant itself, thereby improving the adhesion and thus reducing the likelihood of fatigue or fretting failures. Unfortunately, the corrosion rates of porous titanium, porous CoCrMo, and porous NiTi in simulated body fluids have all been reported as being significantly higher than those of their solid counterparts, possibly due to crevice corrosion within the pore matrix.<sup>61–64</sup>

Very recently, interest has been shown in metallic foams, in which a foaming agent helps to control the porosity that can be up to 80%.<sup>65</sup> It has been reported that, for such titanium foams, corrosion rate as low as  $0.07 \mu\text{m year}^{-1}$  can be obtained after aging for 6 days in a simulated body fluid (0.01 M phosphate buffer pH 7.4, 0.027 M KCl + 0.137 M NaCl), which is comparable with or even better than that of solid titanium.<sup>66</sup> However, since the wetted surface area of a foam is more than 1000 times its geometric area, the concentration of metallic ions released is still much higher from foams than from solid materials, increasing the risk of health problems related to elevated metal levels in body tissues.

### 2.27.5.6 Magnesium Alloys

At first sight, most readers will be surprised at the suggestion of fabricating biomedical devices out of a material that corrodes as readily as magnesium; however, corrosion can in fact be a desirable feature! Preliminary investigations are being conducted into the use of magnesium alloys as degradable implants for musculoskeletal surgery,<sup>67</sup> the idea being that magnesium ions encourage bone cell activation so that the bone slowly regenerates as the metal corrodes. This represents an interesting new challenge to corrosion scientist: how to tailor the corrosion rate of the Mg alloy to match the bone regrowth rate? However, it should be noted that Witte *et al.*<sup>67</sup> reported that *in vivo* corrosion rates were four orders of magnitude lower than *in vitro* rates, and that the order of relative performance between the various Mg alloys tested changed with environment, leading these

authors to conclude that the present ASTM standard *in vitro* corrosion tests are unable to predict the *in vivo* corrosion rates of magnesium alloys.

### 2.27.5.7 Rare Earth Magnets

There are a number of ternary alloys containing rare earth elements that have remarkably strong magnetic properties, such as the samarium–cobalt family. Although originally developed for the magnetic storage industry, these alloys are used in a number of specialized medical applications, for example, as dental keepers; the strong magnetization is used to keep dental fixtures in place. Unfortunately, these rare earth magnets have very poor corrosion resistances and cannot be directly inserted into any body fluid. One solution is to completely seal the magnet inside a stainless steel cladding, but this must not reduce the effectiveness of the magnetization, which rules out the austenitic steels. In the case of dental keepers, ferritic stainless steels with chromium levels as high as 55% have been used, sufficient to withstand the most corrosive foodstuffs. The magnets hold the dental fixture to a ferromagnetic material usually cemented into a residual tooth root; typically this is a Pd–Co alloy offering good corrosion resistance, but there are concerns about the leaching of cobalt ions, which are cytotoxic at high concentrations.<sup>68</sup>

### 2.27.5.8 Dental Amalgams

Dental amalgams are high-strength multiphase alloys, which makes them vulnerable to localized galvanic or intergranular corrosion between the different phases. The majority of modern dental amalgams are prepared from two types of alloys: conventional silver tin amalgam and high-copper amalgams. The high-copper amalgams have superior clinical properties with a higher resistance to corrosion.<sup>69</sup> The corrosion of any amalgam is of concern, as it leads to the release of mercury into the body, and in rare cases, can cause oral lesions if this redeposits in the oral mucosa.<sup>15</sup> In conventional silver tin amalgams, the most base phase is  $\gamma_2$  ( $\text{Sn}_7\text{Hg}$ ), which releases mercury when it corrodes.<sup>70</sup> Conversely, the most corrosion-prone phase in high-copper amalgams is  $\eta'$  ( $\text{Cu}_6\text{Sn}_5$ ), preferential corrosion of which does not release mercury into the body and thus these alloys have recently been favored.<sup>71</sup> However, Joska *et al.*<sup>72</sup> found that mercury release rates from conventional silver amalgams and high-copper amalgams were very similar, the method of preparation being

critical. Furthermore, it has been shown that for most people, the major route for mercury to be taken into the body is via food, less than 10% coming from dental amalgams.<sup>73</sup>

### 2.27.5.9 Titanium Nitride Coatings

Very hard yet smooth, low friction coatings of titanium nitride, typically a few microns thick, can now be produced by a variety of methods, including ion implantation,<sup>38</sup> nitriding,<sup>39,40</sup> physical vapor deposition,<sup>41</sup> and magnetron sputtering.<sup>74</sup> These coatings have been shown to have excellent biocompatibility and have been successfully used on Ti6Al4V to protect against fretting corrosion and other forms of wear, allowing the world's first collar bone replacement to be preformed in 2003,<sup>41</sup> as well as on NiTi alloy and stainless steels to provide protection against pitting and crevice corrosion.<sup>59,75</sup> The excellent combination of biocompatibility with corrosion and wear resistance means that TiN coatings will undoubtedly find increased usage in biomedical applications.

One potential concern about nitride coatings that has yet to be fully investigated is the possibility of galvanic corrosion of the underlying metal at holidays or damaged areas of the coating. This has already been shown to be a problem at microstructural defects in TiN coatings on type 304 stainless steel in saline solutions.<sup>76</sup> Variations on titanium nitride coatings are also being developed, such as titanium aluminum nitride, that reportedly provide better protection to stainless steels without any loss of biocompatibility.<sup>76,77</sup>

## 2.27.6 Corrosion Types Encountered in Biomedical Applications

### 2.27.6.1 General Corrosion

For a successful implant material, the longterm general corrosion rate should certainly fall to much less than  $1\mu\text{m year}^{-1}$ ; for almost any other application, such low corrosion rates would be considered insignificant. Nevertheless, even at these rates, it has been reported that after implantation the nickel, chromium, and cobalt levels in surrounding tissues can be significantly higher than normal values (Table 1).<sup>2</sup> It has also been shown that the presence of metallic ions released from nonmolybdenum-containing high-nitrogen stainless steels suppresses cell growth of human gingival fibroblasts.<sup>78</sup>

### 2.27.6.2 Pitting Corrosion

Although cases of pitting corrosion were common with the early stainless steel implants fabricated from grade 304, the addition of Mo (2–3%) to form 316L grade stainless steel has greatly reduced the number of failures. Zitter<sup>26</sup> has suggested that a PREN greater than 26 is required to prevent *in vivo* pitting corrosion. Stainless steel biomedical devices should thus be manufactured from at least high-quality 316L, preferably from ultraclean grades such as 316LVM or grades containing nitrogen additions. The risk of pitting corrosion of stainless steels in the oral cavity is higher than that in implants because of the number of chloride-containing acidic foodstuffs regularly introduced into the mouth. Although this is partly compensated by the ease by which orthodontic devices can be retrieved, it is still recommended that ultraclean high-nitrogen austenitic stainless steels be used rather than the standard 316L grade.

One of the major concerns about the use of surgical implants based on cobalt–chromium–molybdenum alloys is that pitting corrosion could lead to carcinogens being released into the body. This has resulted in numerous *in vitro* investigations into the pitting behavior of these alloys in pseudo-body fluids, all of which have reported excellent resistance to pitting as long as static conditions are maintained.<sup>64,79</sup> However, pitting corrosion has been observed when the CoCrMo alloys were subjected to either cyclic loads or severe cold working.<sup>80</sup>

Titanium metal is immune to pitting corrosion in any *in vivo* environment likely to be encountered. Although Ti alloys are less resistant, no *in vivo* pitting-related failures have been reported. The pitting behavior of nickel–titanium shape-memory alloys has already been discussed earlier.

### 2.27.6.3 Crevice Corrosion

The most common location of crevice corrosion found in biomedical applications is beneath the heads of fixing screws and it is a very serious problem with stainless steel devices, even when fabricated from high-grade molybdenum and nitrogen-containing alloys. In a survey conducted in 1959, Scales *et al.*<sup>81</sup> found that 24% of grade 316 stainless steel bone plates and screws removed from patients revealed signs of crevice corrosion. Although the introduction of the low nonmetallic inclusion type 316LVM stainless steel and the use of an austenitic microstructure free of any  $\delta$ -ferrite phase have reduced the level of

crevice corrosion problems, these have not been eliminated.

Crevice corrosion on CoCrMo alloys appears to be less of a problem than on stainless steels. Syrett and Davis<sup>82</sup> found no crevice corrosion on specimens removed from dogs and rhesus monkeys after 2 years of implantation. Similarly, Galante and Rostoker<sup>83</sup> found no crevice corrosion on CoCrMo alloy implants removed from rabbits after 1 year, although the latter authors did find single pits in the crevice regions that might have eventually developed into crevice corrosion if given sufficient time.

Crevice corrosion of titanium in neutral chloride environments has only been reported at temperatures in excess of 70°C, that is, it is not expected *in vivo*. As with pitting corrosion, titanium alloys are less resistant to crevice corrosion than is pure titanium, and Galante and Rostoker<sup>83</sup> have reported single pits in the crevice regions of Ti6Al4V specimens implanted in rabbits for 1 year, but no actual crevice corrosion. Despite titanium's excellent resistance to crevice corrosion, it is not the answer to the problem, since its poor shear strength makes it unsuitable for screws and other fasteners, which are the main crevice formers.

Finally, some total-joint implant designs contain metal-on-metal press-fit conical tapers, which are subjected to stress and motion. Retrieval studies have found crevice corrosion at taper connections consisting of CoCrMo alloy heads with both CoCrMo alloy and Ti6Al4V stems.<sup>2,84</sup> Occasionally, titanium alloy stems have been attacked, which suggests that the wearing away of the passive film plays a role, that is, the mechanism is a combination of fretting and crevice corrosion.<sup>36</sup>

### 2.27.6.4 SCC and Hydrogen Embrittlement

To the best of the author's knowledge, neither SCC nor hydrogen embrittlement has been observed on recovered surgical implants. Although retrieved implants may show evidence of cracks, they do not show the physical characteristics associated with SCC, and thus almost certainly, result from mechanical damage either during manufacturing or during the recovery process. The laboratory experiments conducted to date support the presumption that the three classes of common implant alloys (Ti, CoCrMo alloys, and stainless steels) are not susceptible to SCC in *in vivo* environments. The only counter evidence comes from *in vitro* tests conducted under experimental conditions that are highly unlikely to ever exist in any true *in vivo* situation, such as extreme

negative potentials or acidic  $\text{MgCl}_2$  solutions. However, Rodrigues *et al.* have very recently reported the first evidence of hydrogen absorption being implicated in the corrosion of retrieved titanium alloy hip implants.<sup>106</sup>

### 2.27.6.5 Corrosion Fatigue

One of the features that distinguish corrosion fatigue from mechanical fatigue is that the former is strongly dependent on the frequency of the applied loaded, with low-frequency cycles causing the most damage. Unfortunately, many medical devices are subjected to low-frequency loads, for example, simply walking represents a cyclic loading at about 1 Hz on a hip implant, so the threat of corrosion fatigue might be expected to be high. However, in 1975, Bechtol<sup>85</sup> reviewed all types of clinical fatigue-related failures and claimed that the most common root cause of failure was not related to corrosion, but rather to a breakdown of the bone–cement support interface. This leads to a widening of the separation between the metal prosthesis and bone–cement and finally to the deformity of the metal stem. This mechanism was recently supported by von Knock *et al.*,<sup>86</sup> who found no evidence of corrosion on 11 CoCrMo alloy femoral components retrieved after 2–15 years of service and suggested that the majority of the micromotion between the prosthesis and bone occurs at the bone–cement/bone interface.

Likewise, reviews of the literature related directly to corrosion fatigue of prostheses implants by Leclerc<sup>87</sup> in 1982 and Zitter<sup>26</sup> in 1991 both concluded that as long as the manufacture and metallurgical condition of the device conformed to international standards (e.g., ISO 5832 or ASTM F 138), corrosion played only a minor role in most fatigue failures. However, in contrast, Morita *et al.*<sup>22</sup> reported that the fatigue strengths of 316 stainless steel and a CoCrNiFe alloy were considerably less *in vivo* (rabbits) than in air and proposed that this was due to the low dissolved oxygen concentration in body fluids, causing a corrosive action on the alloys. Furthermore, in his 1982 review, Leclerc did note that the longer the prosthesis was implanted in the patient, the greater the role of corrosion, which is significant giving that, as explained in the introduction, it is anticipated that the required service life of surgical prosthesis will increase in the coming decades.

If corrosion fatigue does become an important issue in the future, the importance of material selection and design were emphasized by Piehler *et al.*,<sup>88</sup>

who tested hip nail plates and found that large plates had better corrosion fatigue resistance than did small ones and that Ti6Al4V outperformed 316L stainless steel. The good performance of titanium alloys was also highlighted by Hughes *et al.*,<sup>24</sup> who reported that the corrosion fatigue resistance of titanium was virtually independent of pH over the range 2–7, whereas that of stainless steel declines rapidly below pH 4. These observations are consistent with the findings of Yu *et al.*<sup>89</sup> that corrosion fatigue in stainless steels can be initiated by pitting corrosion. The latter authors also reported that the corrosion fatigue resistance of the common implant alloy Ti6Al4V can be enhanced by nitrogen implantation and heat treatments to produce fine prior- $\beta$  grain sizes.

### 2.27.6.6 Fretting Corrosion and Wear

Because all the successful surgical implant alloys are based on passive metals, any process that wears away the protective oxide film is of major concern. As a result, fretting corrosion represents the most important form of attack on load-bearing prosthesis and all three major classes of alloys used, namely, Ti alloys, CoCrMo alloys, and stainless steels, suffer fretting corrosion, sometimes in combination with crevice corrosion.<sup>90</sup> Fretting corrosion not only results in metal loss but also alters the dimensions of the prosthesis, causing fixation problems and allowing additional micromotions. This in turn can increase mechanical wear and lead to the loss of the surrounding bone–cement or bone, which, besides being a serious problem in itself, increases further the amount of movement of the implant, thereby increasing the likelihood of fatigue-related failures.<sup>85</sup> The situation is made worse by the fact that the corrosion products collect locally as particles that can cause further abrasion of the implant; for example, black titanium oxide debris is often found in the vicinity of implants.<sup>91</sup> The main cause of the shearing micromovements that eventually lead to the fretting corrosion is believed to be the large difference between the elastic moduli of solid metallic implants and the surrounding bone or bone–cement.

Morita *et al.*<sup>92</sup> investigated the wear resistances of a high-nickel version of 316L stainless steel (Fe17Cr14Ni2Mo), a cobalt–chromium–molybdenum alloy (Co28Cr6Mo), and the titanium alloy Ti6Al4V and found that rubbing between metal and ultra-high-molecular weight polyethylene, commonly used as a liner for the sockets into which the ball of hip implants are inserted, only caused the oxide on the Ti6Al4V alloy to suffer damage, that is, the titanium alloy was

the least resistant. Worse, when metal rubbed metal, the oxides on all the three implant alloys were destroyed, even at low loads. Furthermore, the addition of calcium chloride and/or hydrogen peroxide to saline solutions has also been shown to lead to increased fretting corrosion of Ti6Al4V.<sup>93</sup> Since  $H_2O_2$  can be produced as part of the inflammatory response of damaged body tissues, it can be postulated that new load bearing prosthesis are at the most risk of developing fretting corrosion, although the corrosion may subside as the  $H_2O_2$  production ceases, sufficient loosening of the device might occur to induce mechanical fatigue. Efforts to reduce the effects of fretting are based mainly on coatings, usually titanium nitride or aluminum oxide.<sup>38–41,74,94</sup>

Besides wear-resistant coatings, endeavors have been made to reduce the threat of fretting corrosion by improving the binding between the implant and its surroundings, be it bone or bone–cement. Proposals of how to achieve this include engineering the shape, topography, porosity, or composition of the implant to provide either in-growth of tissue or enhanced on-growth of mineralized bone<sup>61,95</sup>; plasma spraying a titanium coating with a specific surface roughness on the surface of the Ti6Al4V<sup>96</sup>; or depositing strongly adhered hydroxyapatite coatings that can fuse with the growing bone. Encouraging results have recently been obtained for silicon-doped hydroxyapatite coatings.<sup>97</sup> Although some reports have suggested that hydroxyapatite coatings do not provide any longterm improvement in fixation,<sup>98</sup> overall clinical results indicate that coated implants perform well, especially in young patients.<sup>2,99</sup> Occasionally, erosion–corrosion problems are encountered on implanted valves and pumps, as with nonbiomedical application, the solution to this problem is to use a more resistant material, such as titanium.<sup>100</sup>

#### 2.27.6.7 Galvanic Corrosion

Galvanic corrosion has certainly caused the failure of a number of biomedical devices. However, the vast majority of these cases were caused by poor quality control or a lack of appreciation of the existence of galvanic couple between apparently similar materials. There have even been examples of galvanic corrosion-related failures arising, because just a single grade 304L screw was used in what was otherwise an all grade 316L construction<sup>101</sup>; since it is not possible to visually distinguish one grade of stainless steel from another, the solution to the problem is careful quality control. When the correct materials

have been used, galvanic corrosion is not normally a problem; however, the poor shear strength of titanium alloys means that it is not suitable for use as fasteners, so there may be times when the production of a galvanic couple is unavoidable. In the event that titanium and any cobalt–chromium–molybdenum alloys or stainless steels are coupled together, it is likely that the former will become the cathode and thus accelerated corrosion of the latter alloys may be anticipated. However, titanium and its alloys are easily polarized and their passive films make them poor cathodes, which in practice means that the extent of accelerated corrosion caused to any metal from coupling to a titanium alloy can be expected to be small. This argument has been confirmed in a literature review by Mears<sup>102</sup> and also for titanium/cobalt–chromium–molybdenum alloy combinations by the *in vitro* experiments of Lucas *et al.*<sup>80</sup> and in clinical use as reported by Jackson-Burrows *et al.*<sup>103</sup> Nevertheless, Rostoker *et al.*<sup>104</sup> found that type 316L stainless steel suffered pitting corrosion in 1% NaCl solution at 37°C when it was coupled to either Ti6Al4V, CoCrMo alloy, or graphite, but no pitting corrosion was found when any two of the other three materials were coupled together.

There is also one further aspect of galvanic corrosion to be considered, that is, any bimetallic couple is of course a small battery in which a current flows between the anode and cathode. Even if this current is too small to cause any significant corrosion problems, these could be sufficient to cause the patient pain, indeed persistent pain resulting from such situations has led to the need to retrieve some biomedical devices.<sup>105</sup> In dental applications, galvanic corrosion of amalgams has been linked to causing oral lesions, which can develop into cancer, particularly in patients with a hyposensitivity to mercury.<sup>15</sup>

#### 2.27.7 Conclusions

The knowledge of corrosion and mechanical properties of materials has allowed the development of a number of extremely successful biomedical alloys. As a result, as long as the chosen materials match the requirements of national and international standards, the likelihood of a surgical implant suffering a corrosion-related failure is very low. The most important remaining areas of concern are fretting and corrosion fatigue. Even here, recent advances in titanium nitride coatings and fixation techniques are extremely encouraging, suggesting that a solution to

at least some of the problems is close at hand. The TiN coatings probably represent the most important advance in the protection of biomedical devices since Leclerc<sup>87</sup> wrote his chapter on surgical implants for the third edition of *Shrier's Corrosion* in 1994. However, TiN coatings have yet to be demonstrated in the tapered joints of some total-joint replacements where a combination of fretting and crevice corrosion can cause failures even in titanium alloys. Moreover, device failure is not the only concern; now that younger patients are receiving implants, the concern that extended exposure to even very low levels of corrosion products could result in medical complications, including cancer, is becoming more and more important. So there is still a continuing need to further reduce corrosion rates.

Furthermore, in recent years advanced materials have been developed that possess properties considered highly desirable for biomedical devices, for instance, porosity, shape-memory, and high magnetism. This trend is likely to continue, as the recent upsurge in funding on life science-related research will produce a number of new materials and devices specifically designed for biomedical applications, such as implanted sensors, automatic drug dispensers, and even micromachines. Techniques to protect these materials without interfering with the very functional properties that make them so desirable have been, and will have to be continually, developed, and occasionally, the biomedical industry will continue to throw out more unusual challenges to the corrosion scientist, as in the case of the sacrificial magnesium alloys being proposed to stimulate bone growth where a controlled corrosion rate is deemed desirable.

### Glossary

**Cellulose** A complex polymeric carbohydrate, the chief constituent of the cell walls of all plants.

**Creosote** Oily liquid containing phenols and creosols, obtained from coal tar or by the destructive distillation of wood tar.

**Heartwood** The inner region of wood in a tree, it is dead.

**Hemicellulose** Plant cell-wall polysaccharides.

**Lignin** A polymeric organic compound consisting of various aromatic alcohols.

**Lumber** Wood that has been cut and surfaced for construction use.

**Lumen** The cavity bounded by a plant cell wall.

**Moisture content** The weight of water in wood expressed as a percentage of the weight of wood fibrous material (which is considered to be the oven dry weight of the sample).

**Polyphenols** Alcohols containing two or more benzene rings, each of which have at least one hydroxyl group (OH) attached.

**Sapwood** The outer layer of wood in a tree, next to the bark.

**Tannins** Soluble astringent complex phenolic substances of plant origin.

**Timber** Lumber whose smallest dimension is not less than 5 in.

**Wood** The hard, fibrous substance that forms the major part of the trunk and branches of a tree.

### Abbreviations

**ACQ** Alkaline copper quat

**AWPA** American Wood Preservers' Association

**CCA** Copper–chromium–arsenic

**DOT** Disodium octaborate

### 2.28.1 Corrosion of Metals by Wood

Wood can cause corrosion of metals with which it is in contact, and nearby metals by emission of acidic vapors. The most important practical consequence of contact corrosion is the failure of fasteners in wood. Vapor corrosion affects mainly items that are packaged, stored, or displayed in wooden containers.

### 2.28.2 Structure and Composition of Wood

Wood is an organic material with a cellular structure and open spaces (lumens) between the cells. There

are many constituents in wood; the structural constituents are cellulose and hemicellulose fibers and lignin. Woods show great variability in terms of mechanical properties and chemical composition between species and within individual samples. Wood is very anisotropic in respect of most of its properties.

In dry wood, water is present only in the cell walls and within the cells; this water is bound and hence not available to support a corrosion process. However, dry wood is hygroscopic and it readily absorbs further water, becoming damp or wet. This water is present in the cell walls and in the lumens; it is free water and is usually present in sufficient quantities to support corrosion of metals in contact with the wood.

Woods are more or less resistant to biological attack; preservative chemicals are used to treat it to control fungal decay and insect attack. It is also flammable and therefore often treated with fire-retardant chemicals.

Woods contain organic acids, principally acetic acid with smaller quantities of formic, propionic, and butyric acids. Indeed, in the early twentieth century, most acetic acid was obtained by distillation from wood.<sup>1</sup> Wood also contains some natural corrosion inhibitors such as tannins. The water, acid, inhibitor, and treatment chemical contents of wood influence its corrosivity toward metallic materials.

### 2.28.2.1 Mechanisms of Corrosion by Wood

Two distinct mechanisms have been identified for the corrosion of metals by wood. These are conventionally called contact corrosion and corrosion by acidic vapor. This discussion applies primarily to the corrosion of iron and steel; corrosion of other metals is addressed in [Section 2.28.2.1.3](#). Indirectly, some of the constituents of wood contribute to corrosion in pulping plants, but this subject is not addressed in this chapter.

#### 2.28.2.1.1 Contact corrosion

Damp wood can be considered as an electrolyte or a slightly acidic solution,<sup>2</sup> hence metals in contact with wood are subject to conventional electrochemical corrosion in which electrons are released at anodic sites and consumed at cathodic sites. Pinion<sup>3</sup> demonstrated the production of alkali ( $\text{OH}^-$ ) at the exposed end of a steel nail in wet wood. This is formed as a result of oxygen reduction in the cathodic reaction of the corrosion process

This process occurs most readily at areas of greatest oxygen access, for example, on the heads of fasteners embedded in wood.

The anodic reaction is metal dissolution, which in the case of iron and steel is

This process occurs on the shanks of fasteners embedded in wood, resulting in damage that is not visible from the outside.

The corrosion of fasteners in wood is often described as a form of crevice corrosion, since metal loss occurs primarily in the area that is shielded from the higher oxygen content environment on the external surface of the wood (and the head of the fastener). However, differential aeration cell corrosion is a better description, because the term crevice corrosion is most commonly applied to corrosion-resistant alloys, for example, stainless steels. Differential aeration cells are reported to occur also on fasteners that connect two different woods,<sup>3,4</sup> resulting in corrosion within the wood of lower oxygen diffusivity.

#### Moisture content

The moisture content of wood is the dominant factor in controlling contact corrosion. As explained by Zelinka *et al.*,<sup>5</sup> in wood with moisture content below ~15–18%, the water in wood is bound to the hydroxyl sites within the cell walls; there is no free water, and therefore, the ionic conductivity of wood is very low and corrosion is minimal. Increasing the moisture content of wood results in free water within the cell walls; this supports the ionic conductivity, permitting corrosion to occur. This critical moisture content of the wood is equivalent to a relative humidity of the atmosphere around the wood of approximately 80–85%, depending on temperature.<sup>6</sup> Note that the critical moisture content varies between woods and a wider range of 10–20% is given in some references.<sup>2,7</sup> This critical moisture content is often described as the threshold for corrosion to occur, but the transition between dry and wet wood, or no corrosion and corrosion, is not so marked as the term implies.

The threshold moisture content for corrosion is also the minimum moisture content required for fungal decay (for which there is an upper limit of ~60% and oxygen must also be present), hence wood that is to be exposed to wet conditions is typically treated with preservatives to prevent such decay.

#### Acid content

The organic acid content of wood is an important factor in contributing to contact corrosion and vapor

corrosion of metals by wood. Acetic acid is the main acid involved, since it is present at significantly higher levels than are the other acids in wood. Acetic acid is formed by the hydrolysis of acetylated polysaccharides in the wood. As little as 0.5 ppmw is sufficient to influence corrosion,<sup>8</sup> with corrosivity increasing roughly in line with acid content, but it is to be noted that pH and other measured properties of wood can vary significantly between samples, between heartwood and sapwood, and across small distances in a single sample.

**Table 1** shows the variable nature of the acidity of woods;<sup>9–11</sup> the pH of aqueous extracts from eucalyptus woods have been found to be 2.5 or even lower.<sup>12</sup> As a rough guide, woods of pH below 4 are very corrosive and woods of pH greater than 5 are low in corrosivity, but other factors are also relevant.

### Salts

Woods naturally have a small salt content, notably sulfate and chloride, but this can increase by a number of means, including marine aerosol deposition, the floating of logs in seawater,<sup>13</sup> the introduction of chemical treatments such as preservatives and fire retardants, and even by the process of salt seasoning.<sup>13</sup> Salts contribute to corrosion by increasing the conductivity of the wood. The role of copper ions, which are an important component of many preservative treatments, is discussed in [Section 2.28.2.4.1](#).

### Polyphenols

Polyphenolic compounds that possess two or three adjacent hydroxyl groups are reported to be capable of forming iron chelates. This chelation, along with the acidity of the wood, is considered to be a contributing factor in the corrosion of steel saw blades.<sup>14</sup>

### Bimetallic corrosion

Contact between dissimilar metals in damp wood results in bimetallic corrosion.<sup>2,15</sup> An example is that of steel-framed boats with wooden planking attached by copper alloy fasteners.<sup>11</sup> This is easily avoided by preventing such contact or selecting compatible fasteners.

### Effect of corrosion on wood

The alkali ( $\text{OH}^-$ ) that is formed at the cathodic site during the corrosion process degrades the wood. Hemicelluloses and lignins are readily attacked by alkali, making the wood spongy. This effect is commonly known as nail sickness<sup>3,16</sup> and results in a loss of holding power of nails and other fasteners in the wood.

At anodic sites, iron corrosion products react with tannin to form blue-black staining. This is a common problem in wooden railway sleepers and it affects other materials of cellulosic structure, including textiles.<sup>17</sup> It also occurs where iron corrosion products from steel wool (used to finish wood) and handling chains come into contact with the wood. Tannate

**Table 1** Relative corrosivity of woods by vapor corrosion

Wood	Classification in Defence Guide-3A <sup>10</sup>	Typical pH values
Oak	Most corrosive	3.35, 3.45, 3.85, 3.9
Sweet chestnut	Most corrosive	3.4, 3.45, 3.65
Steamed European beech	Moderately corrosive	3.85, 4.2
Birch	Moderately corrosive	4.85, 5.05, 5.35
Douglas fir	Moderately corrosive	3.45, 3.55, 4.15, 4.2

staining is generally restricted to a depth of 0.4 mm<sup>18</sup> and hence is not a significant form of degradation.

Some sources suggest that acidic conditions develop at the site of the anodic reaction, by reaction between chloride ions and ferrous ions (though more accurately the acidity will be produced by metal ion hydrolysis),<sup>19</sup> but the significance of this is not well documented.

### 2.28.2.1.2 Corrosion by acidic vapor

The organic acids in wood are volatile and can cause corrosion of some metals in confined spaces. It is principally acetic acid that is responsible for this form of corrosion. The mechanical properties of woods can be enhanced by thermal treatment, but this increases the volatility of organic acids, which increases the risk of vapor corrosion at least in the short term. This form of corrosion was traditionally associated with the use of wooden packaging and pallets, but more recently, it has become a serious issue in conservation.

Aoyama *et al.*<sup>20</sup> attributed the corrosion of nickel-plated brass to acetic acid released from wooden storage boxes. In extreme conditions of heat and humidity, sufficient acetic acid vapor is produced from wood to cause stress corrosion cracking of quenched and tempered AISI 1035 carbon steel nails.<sup>21</sup> The imposition of hardness and tensile strength limits was found to be necessary to prevent such cracking. Volatile corrosion inhibitors such as *m*-dinitrobenzene and anthraquinone have been shown to be effective in suppressing acetic acid vapor corrosion of mild steel in wooden boxes in hot, humid conditions.<sup>22</sup>

A common problem in conservation is the corrosion of artifacts stored in wooden boxes or displayed in wooden showcases. As summarized by Berndt,<sup>23</sup> corrosion is due mostly to the presence of acetic acid vapor, although other chemicals, including formic acid, formaldehyde (which is oxidized by atmospheric oxygen to formic acid), and esters (which hydrolyze to form alcohols and acids) can also contribute. Work conducted at the British Museum has shown that Egyptian bronze artifacts corroded when stored in wooden cupboards due to the presence of acetic acid vapor at levels in the range 1000–2500 mg m<sup>-3</sup>. Subsequent work found that corrosion did not occur on a range of lead and copper alloys when the acid vapor was reduced to below ~350 mg m<sup>-3</sup> in showcases, but this limit is a function of humidity and temperature.<sup>24</sup> Humidity control and acid-scavenging chemicals are used to control this form of corrosion, but the preferred solution is to select materials of construction that release less acidic vapor.

### 2.28.2.1.3 Corrosion of other metals

#### Aluminum

Aluminum alloys have reasonable resistance to corrosion in wood of low moisture content, but it is recommended that they should be protected by coatings or other technique if the wood becomes wet in service.<sup>25</sup> Specific corrosion risks are posed by wood that contains chloride ions (e.g., by absorption from salt water) and by copper-containing and mercury-containing preservative treatment chemicals. This corrosion risk extends to flashing that is exposed to water runoff from treated wood. Some preservatives such as pentachlorophenol and chromates are considered to be innocuous to aluminum, but note that chromate treatments have been largely phased out for environmental reasons. Coal tar creosote is considered to have corrosion-inhibiting properties toward aluminum, but some corrosion testing that forms the basis of some reports has failed to separate out other effects, such as water repellency, associated with creosote.

#### Brass and other copper alloys

Copper and its alloys are susceptible to corrosion by acetic acid, as noted in [Section 2.28.2.1.2](#), and are therefore subject to corrosion in most woods. Brass screws were reported to suffer dezincification in damp wood that had been treated with zinc chloride and sodium dichromate.<sup>26</sup> Copper and its alloys are susceptible to corrosion by ammonia, which is released from ammonium salt fire-retardant treatments in some circumstances.

#### Lead

Lead roofs have been corroded by acetic and formic acid released from wood that has been wet by condensation in poorly ventilated conditions.<sup>27</sup>

### 2.28.2.2 Corrosion Testing

A number of corrosion test methods are applicable to contact corrosion; these are reviewed by Zelinka *et al.*<sup>28</sup>

Simple exposure tests have been standardized by the American Wood Preservers' Association (AWPA). AWPA standard method E12-94 'Standard Method of Determining Corrosion of Metal in Contact with Treated Wood,' is an accelerated test method, in which a metal coupon is placed between two pieces of preservative-treated wood and exposed for 240 h at 49 ± 1 °C, 90 ± 1% relative humidity. The assessment of the test coupons is based on mass loss

and visual appearance. Because the test is accelerated, it cannot be used to predict a service life for a metal component in contact, rather, it is used to rank the corrosivity of preservative treatments. The industry is currently working to develop new tests that will be more directly applicable to the corrosion of fasteners in treated wood. ASTM subcommittee G01.14.01 'Corrosion of Metals in Treated Lumber' is also addressing this issue.

A further AWPAs test is E17-99 'Standard Method for Determining Corrosion Rates of Metals in Contact With Treating Solutions,' in which metal coupons are exposed in the preservative treatment chemicals. This method is applicable to corrosion in treatment plant equipment, and not to corrosion on contact with treated wood.

Electrochemical corrosion test methods have also been employed. Linear polarization resistance measurement has been used successfully to study the corrosion behavior of carbon steel, stainless steel, and zinc in solutions of preservative treatment chemicals<sup>29</sup> and in aqueous extracts prepared from wood.<sup>5</sup> However, it is not a suitable technique for corrosion in contact with wood because of the relatively poor ionic conductivity of wood and it is not capable of measuring localized corrosion effects such as pitting. Alternating current impedance testing is more appropriate for the study of contact corrosion; it has been used with some success on preservative-treated wood.<sup>30</sup> However, Zelinka *et al.*<sup>31</sup> reported that results obtained in their tests could not be related to corrosion rate 'because of gaps in understanding the impedance properties of wood.'

### 2.28.2.3 Corrosion Modeling

The modeling of the corrosivity of wood toward embedded fasteners has been undertaken in Australia,<sup>32</sup> taking into account several factors, including the moisture content and acidity of the wood, temperature, local sheltering, and weathering, in addition to climatic and atmospheric factors. The objective of this modeling is the prediction of the service life of fasteners in wooden structures.

### 2.28.2.4 Industrial Significance of Corrosion of Metals by Wood

Wood is the oldest construction material known to man. It has long been used to construct dwellings, boats, and structures such as bridges, and to manufacture weapons. In the first stages of the Industrial

Revolution, most machines were made of wood.<sup>33</sup> Although its industrial use has declined in recent years, it is expected to increase again now that it has been recognized<sup>34</sup> that wood is an environmentally friendly material with significantly lower energy cost and carbon footprint than steel and concrete in many building applications.

#### 2.28.2.4.1 Building

The most important use of wood within the purview of this book is its use as a construction material for buildings. Wood in ground contact, or exposed to rain or to humid air, has a moisture content sufficient to sustain contact corrosion of metallic fasteners. Corrosion in this condition is often dominated by the effects of preservative or fire-retardant chemicals. The following discussion also applies to other wood in ground contact such as railway sleepers and utility poles, which are routinely treated with these chemicals.

#### Preservative treatments

A range of preservative chemicals are used for the treatment of wood against fungal decay and insect attack. Traditional preservatives include creosotes. Creosotes are low in corrosivity toward most metallic materials except lead,<sup>8</sup> and are often reported as having corrosion inhibiting properties. Coal tar creosote is reported to be less corrosive than is wood tar creosote toward carbon steel.<sup>35</sup> Other organic chemicals such as pentachlorophenol are considered to be noncorrosive.

Many modern preservatives are based on copper compounds, since copper is a potent fungicide. Copper ions introduced into wood are a major contributing factor to corrosion in treated wood, but their role has not been established with certainty. Baker<sup>2</sup> proposed a form of galvanic corrosion between the copper and less noble fastener materials. However, work by Simm *et al.*<sup>36</sup> failed to find metallic copper on the surface of steel fasteners that had corroded in copper–chromium–arsenic (CCA) treated wood, implying that the possible cathodic reaction of  $\text{Cu}^{2+}$  ion reduction was not operative. Copper salts in common use include copper naphthenate, copper azoles, CCA, and alkaline copper quat (ACQ).

CCA preservatives are now less commonly used, since the U.S. Environmental Protection Agency has concluded that their arsenic content may threaten human health. They have been largely replaced by ACQ formulations, which are more corrosive toward steel and galvanized steel. This is considered to be due to the higher level of copper ions in the newer formulations, and because the chromium and arsenic

in CCA acted as corrosion inhibitors. Tests conducted on galvanized steel in accordance with AWWA E12 standard (see [Section 2.28.2.2](#)) showed corrosion rates  $< 0.03 \text{ mm year}^{-1}$  for DOT,  $\sim 0.03\text{--}0.08 \text{ mm year}^{-1}$  for CCA, and  $0.08\text{--}0.16 \text{ mm year}^{-1}$  for ACQ types. Types 304 (UNS S30400) and 316 (UNS S31600) stainless steels performed well in all treatments.<sup>37</sup>

Recommended fasteners<sup>36</sup> for use in wood treated with modern copper-containing preservatives are galvanized steel, with at least  $0.9 \text{ oz ft}^{-2}$  ( $45 \mu\text{m}$ ) of zinc, or stainless steels. Aluminum alloy fasteners are not recommended for this application. Previous work<sup>2</sup> showed that the corrosion resistance of copper and Monel (UNS N04400) in CCA-treated wood was intermediate between that of stainless steels and galvanized (and bare) steel.

Copper-free formulations such as zinc naphthenate<sup>11</sup> and disodium octaborate (DOT,  $\text{Na}_2\text{B}_8\text{O}_{13}\cdot 4\text{H}_2\text{O}$ ) are reported to be noncorrosive.

#### Fire-retardant chemicals

Common fire-retardant treatment chemicals are based on boron compounds (boric acid or sodium tetraborate), zinc chloride, or ammonium salts (sulfate or phosphate). Corrosion inhibitors such as sodium dichromate and ammonium thiocyanate are present in some formulations.

Boron-based treatments are considered not to pose a risk of corrosion to metallic materials in contact with treated wood.<sup>8</sup> Zinc chloride is corrosive, but reports for the ammonium-based treatments are variable.<sup>11</sup>

#### 2.28.2.4.2 Water tanks

Wood is still used for tank construction and may have “the best life cycle cost of any material in handling water, acidic wastewaters, and weak acid solutions up to temperatures of  $60^\circ\text{C}$ .”<sup>38</sup> Corrosion-resistant materials should be used for fasteners and fittings in such tanks.

#### 2.28.2.4.3 Water cooling towers

Wood is the most economic material of construction for some components of water-cooling towers of certain design and capacity. Wood degrades in this service, but fastener failure by corrosion does not appear to be an issue.

#### 2.28.2.4.4 Wood cutting tools

In use, saw blades<sup>11</sup> and other wood cutting tools<sup>39</sup> suffer corrosion and corrosive wear that has an

electrochemical component that ‘is not negligible and can be very important.’

#### 2.28.2.4.5 Conservation

In addition to the issues discussed in [Section 2.28.2.1.2](#), corrosion of metals by wood endangers some of our cultural heritage. Sánchez-Gómez *et al.* report that steel bars embedded in a wooden door to a belfry tower dating back to 1724 corroded, damaging the door.<sup>40</sup>

### Glossary

**Gray** SI unit of absorbed radiation;  $1 \text{ Gy} = 1 \text{ J kg}^{-1}$ .

**G-value** Radiolytic yield in terms of the number of particles formed per 100 eV of absorbed energy.

**LET** Linear energy transfer; measures the energy deposited by ionizing radiation per unit path length in the absorbing medium.

**Rad** Non-SI unit of absorbed radiation dose;  $100 \text{ rad} = 1 \text{ Gy}$ .

**Radiolysis** Chemical decomposition brought about by the absorbance of ionizing radiation.

**$V_{\text{NHE}}$**  Electrode potential, volts with respect to the normal hydrogen electrode

**$X(Y)$**  Element X present in valency state Y; for example, Cr(VI) is  $\text{Cr}_2\text{O}_7^{2-}$  or  $\text{CrO}_4^{2-}$

### Abbreviations

**IASCC** Irradiation-assisted stress corrosion cracking

**LET** Linear energy transfer

**LWR** Light water reactor

**PWR** Pressurized water reactor

### Symbols

**$V_{\text{SCE}}$**  Electrode potential, volts with respect to the saturated calomel electrode

### 2.29.1 The Nature of Ionizing Radiation

Ionizing radiation is produced by a number of processes, such as radioactive decay, nuclear fission, and nuclear fusion. There are many types of ionizing radiation, including neutrons, protons,  $\alpha$ -particles (helium nuclei),  $\beta$ -particles (electrons),  $\gamma$ -radiation, X-rays, and cosmic rays. Ionizing radiation imparts energy to matter with which it interacts, sufficient, by definition, to displace electrons from the matter. The amount of energy absorbed,  $\phi_{\text{ads}}$ , obeys the exponential decay law, depending on the energy of the incident radiation flux, the nature of the radiation, the physical properties of the matter (such as its density), and the depth of the matter through which the radiation passes:

$$\phi_{\text{ads}} = \phi_0 - \phi_0 e^{-\mu x} \quad [1]$$

where  $\phi_0$  is the incident flux,  $\mu$  is the attenuation coefficient (which is specific to the type of radiation and depends on the density of the absorbing matter), and  $x$  is the depth of the absorbing matter.<sup>1</sup> It is

immediately clear why thick sections of dense materials such as lead are used to shield ionizing radiation in order to limit occupational exposures to acceptable levels. The range of charged particles, that is, electrons, protons,  $\alpha$ -particles, and heavier ions, is much shorter and decreases with particle mass. For example,  $\alpha$ -particles will not penetrate through a sheet of paper, and  $\beta$ -radiation is typically completely absorbed by a few millimeters of a light metal such as aluminum. However, heavy charged particles deposit significantly more energy per unit path length than do lighter uncharged particles. This is termed the linear energy transfer (LET) value<sup>2</sup>; LET values for 3 MeV  $\beta$ -radiation, protons, and  $\alpha$ -radiation in water are 0.2, 20, and 150 keV  $\mu\text{m}^{-1}$  respectively.<sup>1</sup>

The SI unit of absorbed radiation is the gray (Gy), which is defined to be the absorbance of 1 J  $\text{kg}^{-1}$  of matter. However, a unit termed 'rad' is still frequently used (1 Gy = 100 rad). Absorbed dose rates are measured in grays per second or, more conveniently, grays per hour. A related unit is the sievert (Sv), which is used to measure absorbed dose equivalents in biological samples, using weighting factors to take into account the different damage effects of the various types of ionizing radiation.

## 2.29.2 Corrosion Effects Arising from Radiation Absorbance

### 2.29.2.1 The Effect on Metals and Surface Films

The majority of the effects of ionizing radiation on corrosion processes are associated with radiolytic alteration of the environment (see Section 2.29.2.2), but a brief mention is made here of effects on the metal substrate and surface films, which may be important, sometimes critically so, in some circumstances.

All types of ionizing radiation may affect the semi-conducting properties of passive films (termed the photoradiation effect) by altering the number and type of charge carriers.<sup>3,4</sup> Cathodic processes may consequently be affected, leading to change in the corrosion rate. However, the photoradiation effect is small and can be confused with the much more significant effect on cathodic processes arising from solution radiolysis.

Heavy, energetic particles (i.e., neutrons and protons) promote atomic displacement and the formation of increased numbers of defects, both in metal lattices and oxide films. A number of important physical properties are affected as a result (e.g., electrical resistivity

and hardness), but as far as corrosion processes are concerned, there are two principal effects, both deriving, in very simplistic terms, from increased defect density arising from atomic displacements:

- the thickness and porosity of oxide films forming on metals such as aluminum and zirconium increases<sup>5,6</sup>;
- some alloying elements may preferentially segregate to grain boundaries at elevated temperatures (i.e., in nuclear reactors), leading, in the case of stainless steels, to radiation-induced sensitization.<sup>7</sup> This may either have significant *in situ* corrosion consequences in the form of susceptibility to irradiation-assisted stress corrosion cracking (IASCC),<sup>8–10</sup> or introduce a legacy effect when, for example, reactor-irradiated stainless steel is subsequently exposed to water containing very low chloride concentrations.

The other principal types of ionizing radiation,  $\alpha$ ,  $\beta$ ,  $\gamma$ , X-rays, and cosmic rays, do not detectably affect the metal microstructure.

### 2.29.2.2 The Effect on the Environment – Radiolysis

Radiolysis is defined as chemical decomposition brought about by the absorbance of ionizing radiation. Significant corrosion consequences can arise from the products resulting from the decomposition of water, solutes, gases, and polymers and, in some circumstances, from the alteration of the valence state of certain solutes.

#### 2.29.2.2.1 Water radiolysis

Water is fragmented by ionizing radiation, resulting in the formation of a range of short-lived intermediates, which react with themselves, water, and some solutes to generate hydrogen, hydrogen peroxide, and to a much lesser extent, oxygen, as stable molecular products<sup>11–13</sup>:

In a completely closed single-phase situation, almost never encountered in practice, the irradiation of pure water produces no overall oxidizing or reducing effect. When, however, the gaseous products are able to escape, a net oxidizing or reducing effect is produced depending on the composition of the cover gas; the former results in the presence of air, oxygen, or argon, whereas the latter results in the presence of excess hydrogen.

Radiolytic reaction schemes are complex, involving a host of interactions that limit the ultimate yield of the molecular products. For example,

It therefore follows that any solute that preferentially reacts with the reducing radicals acts to increase the overall yield of hydrogen peroxide by suppressing reactions [2a] and [2b]; in such circumstances, the radiolytic yield of hydrogen is suppressed. Oxygen does this directly, reactions [3a] and [3b], and  $Cl^-$  does this indirectly, reactions [4a]–[4b].<sup>11,12</sup> The term radical scavenger is used to denote species that act like this.

$Cl^-$  is not consumed in the process, so low concentrations exert a pronounced effect.

The yield of radiolytic species is quantified by *G*-values, which measure the number of molecules decomposed or the number of molecules, ions, or radicals formed per 100 eV of absorbed radiation energy. *G*-values depend on the type of radiation (i.e., its LET value); fast neutrons and  $\alpha$ -radiation produce higher yields of the molecular products than do  $\beta$ - and  $\gamma$ -radiation, the last two being essentially equivalent. Table 1 illustrates these effects for high-purity, high temperature water.<sup>14</sup> The effect of radical scavengers also depends on the type of radiation, it being more pronounced for neutrons than for  $\beta/\gamma$ -radiation. Hence, considerable care must be taken in applying the findings of studies carried out with one type of radiation ( $\gamma$ -rays being frequently used) to situations where other types of radiation may dominate (e.g., reactor cores).

*G*-values are of fundamental importance in elucidating radiolytic mechanisms, usually done using pulse radiolysis techniques, but from a corrosion viewpoint, have little direct relevance, since it is the steady-state concentration of certain species, primarily hydrogen peroxide, that is important. The steady-state concentration depends not only on the net rate of radiolytic formation, which from the *G*-value concept can be seen to be dose rate dependent, but also on any nonradiolytic consumption mechanisms (including corrosion reactions). However, radiolytic production rates, along with kinetic data for relevant chemical and electrochemical (i.e., corrosion) reactions, do have an important application in forming the basis for mechanistic models predicting the corrosion potential in light water reactors (LWRs) (see Section 2.29.3.1).

### 2.29.3 The Effect of Radiolysis on the Corrosion of Metals in Aqueous Environments

A number of important effects of radiolysis on corrosion processes have been discovered as a consequence of the exploitation of nuclear energy, ranging from energy production in water-cooled power reactors, through reprocessing operations, to the disposal of nuclear wastes.

Upon initial irradiation, the potential of platinum and stainless steel electrodes initially falls toward the reversible hydrogen potential, but then rises with increasing dose uptake toward potentials dominated by hydrogen peroxide redox reactions.<sup>15</sup> This behavior reflects the faster diffusion rate of hydrogen to the electrode compared with hydrogen peroxide and the greater radiolytic yield of hydrogen peroxide compared with hydrogen. For most corrosion processes, the oxidizing effect due to the production of hydrogen peroxide dominates.

**Table 1** Radiolytic yields in high-purity, high temperature water

Energy source	LET (eV Å <sup>-1</sup> )	Yields of species (number per 100 eV)

### 2.29.3.1 High Temperature Water – LWRs

The major application here is the primary coolant circuit of LWRs (i.e., normal, as opposed to heavy, water), of which there are two principal types: boiling water reactor (BWR) and pressurized water reactor (PWR), differentiated by whether steam is raised directly in the core or indirectly via separate steam generators. The water temperature varies a little from reactor to reactor, but is  $\sim 300^\circ\text{C}$ . High-purity water is used in BWRs, whereas in PWRs, additions of boric acid are made to control the reactivity of the fuel as it burns (i.e., undergoes fission) with the acidity counteracted by lithium hydroxide.

Various corrosion processes affect reactor operations, the principal ones being

- fuel cladding corrosion, leading to the formation of adherent oxides, which impact on heat transfer;
- general corrosion of stainless steels and inconels, the latter are used in PWR steam generators, leading to the formation of deposits (termed cruds), which can impact on heat transfer rates and also pose a dose uptake issue in areas that require maintenance, since the corrosion products become radioactive as a result of the ingrowth of various isotopes; and
- stress corrosion cracking (SCC), intergranular or transgranular, of structural stainless steels and inconels.

All of the above are affected by water radiolysis. Corrosion in LWRs arguably constitutes the most important application of water radiolysis, and consequently, LWR chemistry has been extensively studied, and continues to be so as new problems emerge and new reactor designs are being considered. The interested reader is directed to the proceedings of recent international conferences on the subject.<sup>16,17</sup>

Within the core of a BWR operating under normal water chemistry (i.e., deoxygenated pure water), water radiolysis results in oxidizing conditions arising from the greater radiolytic yield of hydrogen peroxide compared with hydrogen. Complex models considering the various radiolytic and electrochemical processes and the flow conditions, coupled with direct measurement in a number of instances, indicate that the free corrosion potential of stainless steels is elevated significantly by as much as 250 mV compared with out-of-core exposure.<sup>18,19</sup> This renders 304 stainless steel susceptible to SCC, particularly if sensitized; if not already present as a result of welding operations, sensitization tends to grow in as a result of neutron damage. Irradiation-assisted SCC is

therefore influenced both by microstructural changes and water radiolysis.<sup>8–10</sup> To counteract the radiolytic oxidizing effect, hydrogen–water chemistry has been introduced to BWRs. **Figure 1** shows that small concentrations of hydrogen, of the order of  $5\text{ cm}^3$  of  $\text{H}_2$  per kg, act to suppress almost completely the radiolytic production of oxidizers in the bulk water.<sup>20</sup> In PWRs, a hydrogen overpressure is similarly used, thus ensuring that conditions within the core are generally sufficiently reducing to prevent the attainment of potentials where SCC of stainless steel can occur,  $-230\text{ mV}_{\text{NHE}}$  being accepted commonly as the safe limit.

The effect of crevices (i.e., occluded regions) requires careful consideration, since local electrochemical conditions within the crevice can differ significantly from the bulk. Complex models considering the rates of radiolytic reactions, transport processes, fluid flow, and electrochemical reactions are

**Figure 1** Computed steady-state concentrations of the indicated radiolytic products in PWR conditions as a function of initial hydrogen concentration. Reproduced from Solomon, Y. In *Water Chemistry of Nuclear Reactor Systems*, Bournemouth, UK, 24–27 October 1978; BNES, London, UK, 1979; pp 101–109, with permission from BNES.

used to estimate the potential distribution, since *in situ* direct measurement is not possible. Such models indicate that higher bulk hydrogen concentrations, that is, 20–25 cm<sup>3</sup> of H<sub>2</sub> per kg, are needed to ensure that the corrosion potential at the tip of long crevices does not exceed –230 mV<sub>NHE</sub>; still higher hydrogen concentrations, that is, 50 cm<sup>3</sup> of H<sub>2</sub> per kg, are required to prevent significant acidification at the crevice tip.<sup>21</sup>

High hydrogen concentrations and slightly alkaline conditions also act to reduce the general corrosion rate of stainless steels and inconels, thus reducing activity build-up in the coolant circuit. However, increasing hydrogen concentration appears to increase the SCC susceptibility of inconel alloy 600. There is, thus, a drive to reduce hydrogen concentrations in PWRs slightly in order to limit SCC of alloy 600, while not compromising on either SCC control of stainless steels or crud deposition due to general corrosion within the reactor circuit.<sup>22</sup>

### 2.29.3.2 Chemical Plant Heating/Cooling Waters and Related Environments

Stainless steels, almost exclusively austenitic grades, are widely used in the construction of nuclear reprocessing plant and ancillary items associated with the storage and disposal of radioactive wastes. In these applications, stainless steels are exposed to a variety of environments, including irradiated waters containing low to moderately high concentrations of chloride at ambient to moderately high temperatures. A strong susceptibility to localized corrosion propagating in the form of pitting corrosion has been noted in some circumstances where such tendency would otherwise not be expected, that is, at <10 mg l<sup>-1</sup> Cl<sup>-</sup> and temperatures as low as 30 °C.

All localized corrosion processes consist of discrete initiation and propagation phases, both of which are influenced by the adopted corrosion potential, and hence the redox potential exerted by the environment. **Table 2** shows that the corrosion potential of passive stainless steel in water is strongly elevated by exposure to  $\gamma$ -radiation, but that the corrosion potential is insensitive to the dose rate.<sup>23</sup> This effect is known to be attributable to water radiolysis rather than subtle modification of the metal's passive film, since the corrosion potential shift is reproduced in nonirradiated stainless steels exposed to previously irradiated water. In addition, in contradiction to early interpretation of the radiolytic corrosive effect,<sup>24</sup> it is clear that the observed oxidizing

Source: Ferreira, M. G. S.; Simoes, A. M. P. Eds.; *Mater. Sci. Forum* **1995**, 192–194, 469–476; Work carried out by Marsh, G. P.; and Taylor, K. J. AERE Harwell, under contract to BNFL, reported by Herbert, D.; Whillock, G. O. H.; Worthington, S. E. In *Electrochemical Methods in Corrosion Research V*; Proceedings of the 5th International Symposium, Sesimbra, Portugal, September 5–8, 1994.

effect is due to stable molecular products, rather than the short-lived intermediates, since the latter do not persist outside of the directly irradiated region. Chemical additions of hydrogen peroxide to nonirradiated waters, in fact, produce essentially the same effect on the corrosion potential, including independence on concentration, as illustrated in **Figure 2**.<sup>23</sup> The behavior of hydrogen peroxide in fixing the potential of (passive) stainless steel is consistent with mechanistic studies, which indicate that the potential of inert (i.e., noble or passive) surfaces is determined by the discharge of hydroxyl radicals, OH, resulting from the decomposition of hydrogen peroxide; the hydrogen peroxide concentration in solution is unimportant, provided it is sufficient to give full surface coverage of adsorbed OH.<sup>25</sup> **Figure 2** indicates that for stainless steel, the critical hydrogen peroxide concentration is less than 0.5 mg l<sup>-1</sup>. This mechanism also explains the reported independence of stainless steel corrosion potential on ozone concentration,<sup>26</sup> since OH radicals also arise from the decomposition of ozone in water.<sup>27</sup>

At Cl<sup>-</sup> concentrations of the order of 10 mg l<sup>-1</sup> and temperatures up to 80 °C at least, the elevation of corrosion potential promoted by water radiolysis (or hydrogen peroxide additions) is not, however, sufficient to initiate true pitting corrosion, since the pitting breakdown potential is far too high. The breakdown potential of commercial grades of stainless steel is, in fact, elevated a little, on average, by ionizing radiations due to the elimination of low breakdown potentials from the distribution.<sup>24</sup> The origin of this effect is not known for certain; it may possibly reflect slight passive film thickening or the removal of surface-breaking inclusions, which might otherwise act as pitting sites, or it might somehow be related to the photoinhibition effect.<sup>28</sup> However, if a suitable crevice

**Figure 2** Effect of hydrogen peroxide on the free corrosion potential of 304L stainless steel in 300 mg L<sup>-1</sup> Cl<sup>-</sup> solution at ambient temperature. Adapted from Ferreira, M. G. S.; Simoes, A. M. P. Eds.; *Mater. Sci. Forum* **1995**, 192–194, 469–476; Herbert, D.; Whillock, G. O. H.; Worthington, S. E. In *Electrochemical Methods in Corrosion Research V*; Proceedings of the 5th International Symposium, Sesimbra, Portugal, September 5–8, 1994.

is present, the elevation in corrosion potential promoted by water radiolysis is sufficient to initiate breakdown within the crevice. **Table 3** demonstrates the effect of  $\gamma$ -radiation on the ease of crevice initiation. These data refer to engineered crevices manufactured from 304L stainless steel, tested in water containing 10 mg L<sup>-1</sup> Cl<sup>-</sup> at 30 °C.<sup>23</sup> Although the dataset is incomplete, hampering unequivocal interpretation, a wealth of other data collected on different stainless steels at different temperatures and dose rates confirms a dose rate effect. The dependence on dose rate, despite the independence of the initial potential elevation, is due to the metastable nature of crevice initiation; without sufficient maintenance of the potential provided by the cathode, an incipient crevice can be switched off by the potential fall accompanying the burst of anodic dissolution.

In the propagation phase of crevice/pitting corrosion, the additional cathodic reaction provided by the reduction of hydrogen peroxide, generated either radiolytically or due to deliberate addition, increases the propagation rate. This is illustrated in **Figure 3** by recording the current flow from a large passive stainless steel surface to an engineered crevice in the presence and absence of  $\gamma$ -radiation.

Once initiated, crevice corrosion propagates in essentially the same manner as pitting corrosion. However, the existence of the crevice is crucial;

Source: Ferreira, M. G. S.; Simoes, A. M. P. Eds.; *Mater. Sci. Forum* **1995**, 192–194, 469–476; Work carried out by Marsh, G. P.; and Taylor, K. J. AERE Harwell, under contract to BNFL, reported by Herbert, D.; Whillock, G. O. H.; Worthington, S. E. In *Electrochemical Methods in Corrosion Research V*; Proceedings of the 5th International Symposium, Sesimbra, Portugal, September 5–8, 1994.

without it, the deleterious effect of the ionizing radiation on stainless steel exposed to low Cl<sup>-</sup> concentrations does not happen. Experience indicates that even very minor defects such as a slight rolling lap or microporosity at a weld, which would not be expected to be detectable at the manufacturing stage, can act as the required crevice, provided the radiation dose rate is high enough. **Figure 4** presents an example. At lower radiation dose rates, a more

severe crevice would be expected to be required to initiate sustained propagation (all other factors such as  $\text{Cl}^-$  concentration and temperature being equal). There are insufficient data and the interactions are too complex to be definitive as to whether there is a dose rate threshold, below which crevice effects cease to be of practical significance. However, as noted earlier, the transition from initiation to stable propagation requires a vigorous cathode, otherwise, the potential drops too far and the corrosion switches off.

**Figure 3** Effect of  $\gamma$ -radiation ( $1 \text{ kGy h}^{-1}$ ) on the current flowing to an AISI 347 crevice in  $100 \text{ mg L}^{-1} \text{ Cl}^-$  solution at ambient temperature. Reproduced from Ferreira, M. G. S., Simoes, A. M. P., Eds.; *Mater. Sci. Forum* **1995**, 192–194, 469–476; Work carried out by Marsh, G. P.; and Taylor, K. J. AERE Harwell, under contract to BNFL, reported by Herbert, D.; Whillock, G. O. H.; Worthington, S. E. In *Electrochemical Methods in Corrosion Research V*; Proceedings of the 5th International Symposium, Sesimbra, Portugal, September 5–8, 1994.

It is in fact the case that all examples, known to the author, of a clear effect on crevice initiation/propagation come from high dose rate environments ( $>100 \text{ Gy h}^{-1}$ ).

Mitigation options are essentially the same as those that pertain to nonirradiated situations. Reducing the  $\text{Cl}^-$  concentration and temperature have strong beneficial effects in reducing the likelihood of crevice initiation; the former has a secondary effect on radiolyzed waters if reduced low enough, since the radical scavenging action of  $\text{Cl}^-$  is eliminated. Inhibitors such as hydroxide and nitrate can also be effective if applied at the outset, but for the latter, at least, consideration needs to be given to its radiation stability (which also precludes organic inhibitors from serious consideration). The selection of a more resistant alloy, such as 316L stainless steel, would also eliminate irradiation-assisted crevice corrosion except at high  $\text{Cl}^-$  concentration.

Although the earlier discussion focuses on stainless steels, there is no reason to suppose that similar radiation effects would not be manifest in other alloy systems where the elevation of the corrosion potential by a few hundred millivolts is required to initiate crevice. However, there appear to be no reported occurrences owing, presumably, to an absence of industrial applications. Likewise, a deleterious effect of radiolysis on other localized corrosion mechanisms, notably SCC and corrosion fatigue, would be expected, but appears not to be reported except in high temperature, high-purity waters (see [Section 2.29.3.1](#)) and for the pond-storage of some types of spent nuclear fuel where the stainless steel cladding is highly sensitized as a consequence of in-reactor damage.<sup>29</sup>

**Figure 4** Corrosion pit resulting from crevice corrosion at a rolling lap on an AISI 321 stainless steel plate exposed for 13 Gy to irradiated water ( $\sim 500 \text{ Gy h}^{-1}$ ) containing  $\sim 10 \text{ mg L}^{-1} \text{ Cl}^-$  at  $\sim 40^\circ \text{C}$ : (a) external appearance (the bright scratch-like feature is the initiating defect); (b) radiograph showing the extent of pit growth; (c) cross-section through the initiating defect. The plate in question was only 4.7 mm thick and the pit did not penetrate to the outside; instead, a relatively large exit hole formed on the same side as the corrosion started from about half way down the pit.

### 2.29.3.3 Nitric Acid Solutions

Nitric acid solutions are used in nuclear fuel reprocessing, exploiting the propensity of uranium and plutonium to form nitrate complexes that dissolve in nucleophilic solvents such as tri-*n*-butyl phosphate. Stainless steels, mainly austenitic grades, are commonly used in the construction of reprocessing plant and are either passive or suffer intergranular corrosion (leading to grain dropping, and hence general wastage rather than cracking), depending on the oxidizing power of the solution, which is strongly increased at high temperatures ( $>70^{\circ}\text{C}$ ) and in the presence of certain dissolved species, which act as oxidants. A more detailed exposition is given elsewhere (see **Chapter 2.24, Corrosion in Nitric Acid**).

Radiolysis of aqueous nitric acid, and indeed, neutral nitrate solutions, produces the nitrite ion as the principal dissolved product,<sup>30</sup> along with varying amounts of hydrogen peroxide, depending on the acidity, since nitrous acid is oxidized by hydrogen peroxide (at least, at room temperature; in hot nitric acid solutions, hydrogen peroxide decomposes with the production of  $\text{NO}_x$  gases, indicating the reduction of the nitrate ion, that is, reversal of the redox couple). The reaction schemes are complex, involving various linked chemical reactions as well as radiolytic ones, and the yields depend strongly on the LET of the radiation.<sup>30</sup>

The presence of significant concentrations of nitrous acid modifies the corrosive behavior of nitric acid considerably, the overall effect depending on the circumstances. In pure aqueous nitric acid solutions, nitrous acid catalyzes nitrate reduction and, therefore, acts to elevate the corrosion potential of stainless steel, increasing its corrosion rate a little if the temperature is high enough to support intergranular corrosion, even though the redox potential of the solution falls, since nitrous acid is less oxidizing than nitric acid (see **Figure 12** in **Chapter 2.24, Corrosion in Nitric Acid**). In more complex liquors containing certain dissolved species such as  $\text{Cr(VI)}$  and  $\text{Ce(IV)}$ , the effect of nitrous acid production can be profound, sharply reducing the corrosion rate if a complete reduction to  $\text{Cr(III)}$  and  $\text{Ce(III)}$  occurs, since the corrosion potential moves back toward passivity.<sup>31</sup> In such liquors, the corrosion potential and hence the corrosion rate attained depends on the overall redox balance; whether oxidation by the acid or reduction by irradiation predominates depends on the nitric acid concentration and temperature, the increase of either of which favors oxidation, and radiation dose rate, the increase of which favors reduction.

Owing to the fact that the corrosion resistance of metals such as zirconium and tantalum is unaffected by oxidizing species in solution, no effect of radiolysis is apparent. No effect of radiolysis on the corrosion resistance of titanium has been reported, although a deleterious effect might be expected if reliance were placed on oxidizing ions, rather than dissolved titanium ions, for the maintenance of passivity (see **Chapter 2.24, Corrosion in Nitric Acid**).

### 2.29.3.4 Polymer Degradation Products

Polymeric materials are susceptible to radiolytic degradation and some, notably halogenated ones, release species capable of exerting strong corrosive effects in some circumstances. For example, the radiolysis of polyvinyl chloride (PVC) produces hydrogen and chlorine free radicals as primary products, which combine producing  $\text{HCl}$ ,  $\text{Cl}_2$ , and  $\text{H}_2$ .<sup>32</sup> Likewise, fluoropolymers produce  $\text{F}_2$  and  $\text{HF}$  (if either hydrogen is present within the polymer or water is present) as potential corrodants. In general, owing to the fact that the release rates are relatively low, significant corrosive effects arise only in situations where the corrodants are able to accumulate. For example, the use of PVC tape to attach temporary signage during the construction of stainless steel plant, which will subsequently be irradiated, is usually banned owing to concerns over the possibility of chloride-induced SCC.

### 2.29.4 The Effect of Radiolysis on the Corrosion of Metals in Atmospheric Environments

In addition to hydrogen peroxide production due to radiolysis of condensed water films, atmospheric corrosion processes may be affected by the production of ozone, nitrogen oxides, and nitric acid from radiolysis of air. In air, most of the observed effects are attributable to nitric acid production, hence, the corrosion rate of metals, which are attacked by dilute nitric acid (e.g., iron, copper, lead, aluminum, zinc, nickel), is increased, whereas metals passivated by nitric acid, such as stainless steels (but see later text), are unaffected.<sup>33</sup> The radiolytic reaction scheme is complex, but nitric acid results from interactions such as

Nitric acid is produced only if water, nitrogen, and oxygen are simultaneously present. Hence, no corrosion acceleration results in irradiated dry air,<sup>33,34</sup> or in irradiated moist oxygen-free nitrogen.<sup>33</sup> Radiation shifts the critical relative humidity required to support atmospheric corrosion to much lower value, 10–20%, compared with 60–70% in the absence of radiation.<sup>35</sup> In general, increasing dose rate increases the corrosive effect, although at very high dose rates, surface temperatures can increase sufficiently to prevent the formation of condensed water films, in which case, no corrosion results.<sup>33</sup> It is also reported that there is a lower dose rate threshold ( $\sim 50 \text{ Gy h}^{-1}$ ), below which negligible corrosive effect results on iron,<sup>33</sup> although the evidence presented to support that assertion appears weak.

Subtle effects arising from the radiolysis of air have been noted, such as an inhibiting effect (due to the nitrate ion) on the initiation of crevice corrosion in stainless steels tested in low  $\text{Cl}^-$  water. However, the principal application relates to potential, deleterious effects during the storage and disposal of spent nuclear fuels and wastes.<sup>36</sup> Stainless steel fuel cladding, if severely sensitized as a consequence of neutron damage, is known to be susceptible to intergranular attack in moist air; the corrosion mechanism appears to be SCC, constituting the only practical example, known to the author, of the occurrence of this failure mechanism in the stainless steel–nitric acid system. In the absence of severe sensitization (i.e., in excess of that produced by normal welding operations), no corrosion occurs.

## 2.29.5 Corrosion Test Considerations

Careful consideration needs to be given to the design of tests employing radiation if representative radiolytic effects are to be adequately produced. This includes the selection of the dose rate and the type of radiation, since the steady-state radiolytic yield of hydrogen peroxide (which is the principal active agent modifying aqueous corrosion) depends on both. However, it appears to be generally the case that sufficiently representative effects are produced by radiation dose rates of the same order of magnitude as those that pertain in the environment being simulated. Likewise, it is the case that different types of radiation generally produce similar radiolytic effects, although the exact effect may be more or less pronounced depending on LET values.

Consideration also needs to be given to the selection of suitably radiation-resistant materials for

the construction of the test apparatus to avoid inadvertent contamination of test liquors by released polymeric degradation products or, in the case of electrochemical tests, to avoid problems arising from the breakdown of electrical insulation. Where necessary, local shielding can be employed to protect items that cannot be made intrinsically more robust. With regard to electrochemical testing, it appears to be the case that  $\gamma$ -radiolysis exerts negligible effect on the stability of saturated calomel or silver/silver chloride reference electrodes.

## Abbreviations

**ADC** Analog to digital converter  
**CE** Counter electrode  
**CSE** Copper sulfate reference electrode  
**EIS** Electrochemical impedance spectroscopy  
**EN** Electrochemical noise  
**IR** Voltage produced by current  $I$  passing through resistance  $R$   
**K-K** Kramers-Kronig  
**OCPD** Open circuit potential decay  
**PSD** Power spectral density  
**RE** Reference electrode  
**SCE** Saturated calomel reference electrode  
**WE** Working electrode

## Symbols

**A** Area ( $\text{m}^2$ ), gain of operational amplifier  
 **$b$**  Bandwidth of measurement ( $\text{s}^{-1}$ )  
 **$B$**  Stern-Geary coefficient (V)  
**C** Capacitance (F)  
 **$C_{dl}$**  Double layer capacitance ( $\text{F m}^{-2}$  or F)  
 **$d$**  Separation between conductors (m)  
 **$e_-$**  Inverting input to operational amplifier  
 **$e_+$**  Non-inverting input to operational amplifier  
 **$e_o$**  Output from operational amplifier  
 **$E_n$**  Electrochemical potential noise (V)

**$f$**  Frequency ( $\text{s}^{-1}$ )  
 **$f_n$**  Characteristic frequency ( $\text{s}^{-1}$ )  
**G** Amplifier gain  
 **$i$**  Current density ( $\text{A m}^{-2}$ )  
 **$i_{corr}$**  Corrosion current density ( $\text{A m}^{-2}$ )  
 **$I_n$**  Electrochemical current noise (A)  
 **$I$**  Current (A)  
**L** Inductance (H)  
 **$q$**  Characteristic charge (C)  
**Q** Charge (C)  
**R** Resistance ( $\Omega$ )  
 **$R_n$**  Electrochemical noise resistance ( $\Omega \text{ m}^2$  or  $\Omega$ )  
 **$R_p$**  Polarization resistance ( $\Omega \text{ m}^2$  or  $\Omega$ )  
 **$R_s$**  Solution resistance ( $\Omega$ )  
**V** Voltage (V)  
 **$V_C$**  Control voltage (V)  
 **$V_{CE}$**  Voltage of counter electrode (V)  
 **$V_i$**  Input voltage (V)  
 **$V_o$**  Output voltage (V)  
 **$V_{RE}$**  Voltage of reference electrode (V)  
**Z** Impedance (complex)  
 **$\Delta E$**  Small change in potential (V)  
 **$\Delta i$**  Small change in current density ( $\text{A m}^{-2}$ )  
 **$\epsilon$**  Relative permittivity  
 **$\epsilon_0$**  Permittivity of free space ( $8.854187817 \times 10^{-12} \text{ F m}^{-1}$ )  
 **$\rho$**  Resistivity ( $\Omega \text{ m}$ )  
 **$\sigma_E$**  Standard deviation of potential (V)

$\sigma_I$  Standard deviation of current (A)  
 $\Psi_E$  Power spectral density of potential ( $V^2 \text{ Hz}^{-1}$ )  
 $\Psi_I$  Power spectral density of current ( $A^2 \text{ Hz}^{-1}$ )  
 $\omega$  Angular frequency ( $\text{s}^{-1}$ )

### 2.30.1 Introduction

This chapter commences by providing a brief summary of the basics of electricity and electrical measurements. It then considers the various measurements involved in the study of electrochemistry and how these can be applied to the study of corrosion. Finally the design of test electrodes and electrochemical cells is discussed. For a more comprehensive introduction to electrochemical methods for corrosion studies, the readers are referred to Kelly *et al.*<sup>1</sup>

### 2.30.2 Basics of Electricity

#### 2.30.2.1 Charge

Charge is the most fundamental electrical property. It derives from the charge inherent in the electrons and protons that make up the atoms and molecules of metals, solutions, and gases that we are concerned with. The unit of charge is the Coulomb, named after Charles Augustin de Coulomb, with the symbol C. The charge on the electron is  $1.602176487 \times 10^{-19}$  C, and therefore, one coulomb corresponds to  $6.24151 \times 10^{18}$  electrons (strictly, the charge on the electron is negative, and therefore, that should really be  $-1$  C).

#### 2.30.2.2 Current

Current is the flow of charge and a current of one Ampere (named after André Marie Ampère, and usually abbreviated to Amp) corresponds to 1 C passing a given point in an electrical circuit in 1 s. Currents in metals invariably consist of movement of the mobile valence electrons. The movement is surprisingly slow (typically of the order of  $10^{-4} \text{ m s}^{-1}$ ), since there are a lot of valence electrons available. Note that the electrons move in the opposite direction to the ‘conventional current,’ which is treated as being due to the movement of positive charges. Currents in solutions consist of the flow of ions, both positively and negatively charged, with positive ions moving in the direction of the conventional current and negative ions moving in the opposite direction.

#### 2.30.2.3 Current Density

In electrochemical systems in which reactions are occurring at the same rate over the entire electrode surface, it is useful to normalize measured currents by dividing by the area to give the current density (units  $\text{A m}^{-2}$ ). In this chapter, we use the convention that  $I$  stands for current, while  $i$  stands for current density. Note that it is not always reasonable to quote current densities; for example, in electrochemical noise measurements (see the following section), current is not expected to be proportional to area, and hence current density is area-dependent. Similarly, it is misleading to refer to current density in relation to pitting or crevice corrosion (except when referring to true current densities, such as the local current density at the corroding surface within the pit or crevice, or the cathodic current density at the external surface).

#### 2.30.2.4 Potential

The potential at a point is defined as the work done in moving unit positive charge to that point from infinity. It is clearly a theoretical concept rather than anything that can really be used! The unit of potential is volt (named after Alessandro Volta), abbreviated as V, and the potential at a point is 1 V if 1 W is required to move a positive charge of 1 C to that point.

#### 2.30.2.5 Potential Difference and Voltage

The potential difference or voltage between two points is the difference between the potentials at the two points. The basic principles of thermodynamics imply that this is identical to the work done in moving unit charge from one point to the other (which we can measure, at least in principle).

#### 2.30.2.6 Resistance and Resistivity

It is commonly found that the voltage across a component is proportional to the current passing through the component. This behavior is known as Ohm’s Law (named after Georg Simon Ohm), given by the well-known formula  $V = IR$ , where  $V$  is the voltage (V),  $I$  the current (A), and  $R$  is the conventional symbol for the *resistance* of the component, with the unit Ohm and the symbol  $\Omega$ . It should be appreciated that, like many laws, Ohm’s Law is an

approximation to reality, and many components (including semiconductors and metal–solution interfaces) do not exhibit a linear relationship between current and potential. When Ohm's Law is not obeyed, we can still talk about the resistance of a component, defined as the slope of the voltage-versus-current curve, but the value of the resistance will vary according to the applied voltage or current.

The resistance of a uniform conductive solid decreases as the cross-sectional area increases and as the length decreases. We can define the *resistivity* of the solid as the resistance across opposite faces of a unit cube of the solid. Then the resistance of a section of wire will be  $l\rho/A$ , where  $l$  is the length of the wire (unit m),  $A$  the cross-sectional area ( $\text{m}^2$ ), and  $\rho$  the *resistivity* ( $\Omega \text{ m}$ ).

### 2.30.2.7 Conductivity and Conductance

In some situations, it is convenient to work in terms of the conductance of a component or the conductivity of a metal or solution. These are simply the inverse of the resistance and resistivity respectively. The unit of conductance is  $\Omega^{-1}$ , also known as Siemens (after Ernst Werner von Siemens), with the symbol S, while conductivity has the unit  $\Omega^{-1}\text{m}^{-1}$  or  $\text{Sm}^{-1}$ .

A particular application of conductance is found in the relationship of the conductivity of a solution to the composition. For dilute solutions, each ion contributes a specific amount to the conductivity, and therefore, the conductivity can be derived by summing the conductivities due to the individual ions making up the solution (see **Chapter 2.38, Modeling of Aqueous Corrosion** for further details).

### 2.30.2.8 Capacitance

If two conductors are placed close together, a change in the voltage between the conductors will lead to a separation of charge, and the amount of charge will be proportional to the voltage. This leads to the concept of a capacitor, a device that stores charge, the governing equation being  $Q = CV$ , where  $Q$  is the stored charge (C),  $V$  the voltage across the capacitor (V), and  $C$  the capacitance (it is unfortunate but inescapable that  $C$  is commonly used as both the symbol for capacitance and for the unit of charge). The unit of capacitance is Farads with the symbol F (after Michael Faraday), and a 1 F capacitor will store 1 C when 1 V is applied across it.

Note that if we differentiate the governing equation for a capacitor with respect to time, we obtain

$$\frac{dQ}{dt} = I = C \frac{dV}{dt}$$

that is, the current is proportional to the rate of change of voltage across the capacitor.

One of the simplest forms of capacitor consists of two parallel plates of conductor separated by an insulator, known as a 'parallel plate capacitor.' In this case, the capacitance is defined by  $C = A\epsilon\epsilon_0/d$ , where  $A$  is the area ( $\text{m}^2$ ),  $\epsilon$  is the relative permittivity of the insulator (dimensionless),  $\epsilon_0$  is the permittivity of free space ( $8.854187817 \times 10^{-12} \text{ F/m}$ ), and  $d$  is the separation between the conductors (m) (strictly this formula is approximate, because it ignores edge effects).

An example of a parallel plate capacitor that is found in electrochemical systems is metals covered with insulating films immersed in solution. In this case, the metal and the solution form the two plates, while the coating provides the layer of insulator.

In the absence of an insulator, there is also a capacitance between a metal and a solution, known as the double-layer capacitance (see **Chapter 1.02, Electrochemistry** for further information).

### 2.30.2.9 Inductance

As current flows along a conductor, it induces a magnetic field. When the current changes, this magnetic field must also change and a voltage is required to cause this change. The inductance,  $L$  (unit Henry, symbol H, named after Joseph Henry), of a component is defined by

$$V = L \frac{dI}{dt}$$

While a capacitor can be thought of as storing charge, an inductor effectively stores current (i.e., once a current is flowing, the inductor tries to keep it flowing). This leads to problems when switching inductive loads, such as motors, as the inductor will develop a large voltage as it tries to keep the current flowing through the switch. This can lead to arcing and damage to the switch contact, together with the production of high-frequency electromagnetic radiation that can be picked up as interference.

### 2.30.2.10 Impedance

Resistance, capacitance, and inductance all represent the response of a component to applied voltage or current, and they can be combined into a single property, the impedance of the component. We can consider a simple example of impedance by thinking

about the properties of a paint-coated metal immersed in solution. An ideal paint will be a perfect insulator, but real paints will display some conductivity. Thus, a paint of thickness  $d$  and area  $A$ , together with the metal and solution either side of it, will exhibit a resistance given by  $\rho d/A$ , while the capacitance, which will be in parallel with the resistance, will be given by  $A\epsilon\epsilon_0/d$ . Note that the resistance decreases with increasing area, whereas the capacitance increases.

The impedance of a resistor is independent of frequency and has a magnitude that is equal to the resistance, and a phase shift of zero.

The magnitude of the impedance of a capacitor decreases with increasing frequency, being given by  $1/\omega C$ , where  $\omega$  is the angular frequency, and the phase shift is  $-\pi/2$  radians ( $-90^\circ$ ).

The magnitude of the impedance of an inductor increases with increasing frequency, being given by  $\omega L$ , and the phase shift is  $\pi/2$  radians ( $90^\circ$ ).

### 2.30.2.11 Admittance

Just as we can consider conductance to be the inverse of resistance, admittance is the inverse of impedance.

### 2.30.2.12 Measurement Fundamentals

All electrochemical studies involve the measurement and/or control of current and voltage. In this section, the fundamental requirements for accurate measurements are presented. Measurements come in a variety of forms:

- Analog or digital

Analog signals have a continuous range of possible values; almost all real variables (current, voltage, velocity, etc.) are analog. It is essentially impossible to measure the value of an analog variable completely, as this would require an infinite resolution. The term analog, when applied to measurements, therefore implies not that the measurement reproduces the measured property completely, but rather that it does not have clearly defined measurement limits. Thus, a conventional electromechanical chart recorder can be described as analog, in that the pen can adopt any position across the chart and the chart paper nominally moves continuously. In practice, the resolution is limited by many factors, including the size of the pen tip, the grain in the chart paper, noise in the measurement electronics, and steps in the chart motion (it is common for the chart drive to use a stepper motor which moves in small discrete steps).

Digital signals have a well-defined set of possible values. The number of values is frequently defined by the number of bits (binary digits) used to represent all of the possible values (since digital instruments often use binary arithmetic internally). One bit can have two possible values (0 and 1), eight bits can have 256 ( $2^8$ ) possible values (00000000 to 11111111), and in general  $n$ -bit numbers provide  $2^n$  possible values. Common resolutions that are available in measuring systems are indicated in [Table 1](#). Not all instruments use binary arithmetic, and many devices such as multimeters that are primarily intended for human interpretation use decimal arithmetic. In this case, the resolution is defined in terms of the number of decimal digits.

- Continuous or sampled

Besides having a finite set of possible values, real measurements also have limited resolution in time. In the case of analog measurements, this usually corresponds to a drop in sensitivity to rapid changes, while for digital measurements, it corresponds to a finite sampling rate. Note that the process of sampling data has important consequences on their quality. In particular, all signal frequencies at or above half the sampling frequency will be converted to false signals below the sampling frequency by a process known as aliasing, and these must be removed by analog filtering ([Section 2.30.2.12.4](#)) before sampling.

**Table 1** Common digital measurement resolutions (as is common, for binary measurements 1 bit is assumed to be used to signify the sign of the measured voltage, while for decimal instruments the sign is additional to the number of digits)

<b>Binary</b>		
Number of bits	Number of values	Resolution for $\pm 1$ V full scale
8	256	7.8 mV
10	1024	2 mV
12	4096	400 $\mu$ V
16	65 536	30 $\mu$ V
20	1 048 576	2 $\mu$ V
24	16 777 216	120 nV
<b>Decimal</b>		
Number of Digits	Number of values	Resolution for $\pm 1$ V full scale
3	1000	1 mV
3.5	1999	500 $\mu$ V
4	10 000	100 $\mu$ V
4.5	19 999	50 $\mu$ V
5	100 000	10 $\mu$ V
6	1 000 000	1 $\mu$ V
7	10 000 000	100 nV
8	100 000 000	10 nV

### 2.30.2.12.1 Time and frequency domains

We experience the world as a sequence of events that follow on in time, and it is natural to think in the ‘time domain,’ that is, the variation of the measured parameters with time. However, the properties of many systems can be understood and interpreted more easily when expressed as the behavior at different frequencies, that is, in the ‘frequency domain’ (the brain works in the frequency domain when processing sound – we hear the different frequencies in the sound, rather than the moment to moment fluctuations in air pressure).

### 2.30.2.12.2 Instrumentation fundamentals

In this section, we shall briefly review the various components that make up modern electronic instruments. This is not intended to be a full coverage of the subject, for which the readers are referred to specialist works, but rather to give a general understanding of the basis.

### 2.30.2.12.3 Amplifiers

A common requirement in instruments is to change the amplitude of a signal or to convert from a current to a voltage or vice versa. This function is performed by amplifiers. In general, the relationship between the input and the output of an amplifier can be defined by its ‘transfer function.’ To simplify the discussion, we shall just consider voltage amplifiers (i.e., devices that take an input voltage  $V_i$  and produce an output voltage  $V_o$ ). Then the transfer function of an amplifier can simply be defined by  $V_o = G(V_i)$ , where  $G$  is the gain of the amplifier. We have written  $G$  as a function in order to emphasize that  $G$  may not be a constant multiplier. Thus the amplifier may be nonlinear over voltage and/or frequency. However, amplifiers are often designed to be linear for voltages and frequencies within their design range, and we can therefore write  $V_o = GV_i$ , where  $G$  is a constant. Thus, an amplifier with a gain of 1000 will convert a 1 mV signal to a 1 V signal.

There is no reason why  $G$  must be positive or greater than 1; thus, it is perfectly feasible to design an amplifier with a gain of  $-0.1$ , which would convert a 1 mV signal to  $-0.1$  mV.

Other important properties of an amplifier are the input and output impedance. The input impedance is the impedance that the input presents to the circuit to which it is connected – for voltage amplifiers we often want this to be very high so that the connection of the amplifier does not affect the system to which it is connected. The output impedance is an indication of the way in which the output voltage is affected by the impedance of the circuit to which it is connected.

We usually want amplifiers to have a low output impedance so that the output voltage is unaffected by the circuit to which it is connected. An important type of amplifier is the ‘unity-gain buffer’; this has a gain of 1 (so the output is the same as the input), but the input impedance is very high, and the output impedance very low. This allows us to connect high-impedance voltage sources (such as the potential measured on a painted sample) to low-impedance measuring devices. A practical realization of a unity-gain buffer is described in the following section.

In contrast to voltage amplifiers, a current amplifier takes an input current, and we want it to have a very low input impedance, so that connecting the amplifier does not affect the current, while a current output should have a very high output impedance, so that the current is not affected by the impedance of the system to which it is connected. Note that there is no reason why an amplifier should not have a current input and a voltage output; indeed this is exactly the characteristics of a ‘zero-resistance amplifier’ (in a later section). Similarly, an amplifier can be designed with a voltage input and a current output, producing a device that provides a current that is controlled by an input voltage (i.e., a voltage-controlled galvanostat).

### 2.30.2.12.4 Filters

Another important building block of modern instruments is the filter. This is a device that responds differently to different frequencies. The simplest filter consists of a resistor and a capacitor (Figure 1). At high frequencies (above  $1/2\pi RC$  Hz), the capacitor has a low impedance compared with the resistor, while at low frequencies it has a high impedance. Then a low pass filter (one that allows low frequencies to pass but removes high frequencies) can be obtained by placing the resistor in the signal path and the capacitor across it (Figure 1(a)). Swapping the two components produces a high pass filter (Figure 1(b)). (The black triangle at the bottom of each figure is a conventional symbol for the earth or ground connection, voltages being assumed to be measured with respect to ground.)

Figure 1 RC filter circuits.

Simple filters using only passive components (resistors, capacitors, or inductors) are rather limited, and many practical filters will use either analog amplifier circuits or digital techniques, which permit a wide range of transfer functions to be produced (see Horowitz and Hill<sup>2</sup> for further information).

## 2.30.3 Measurement and Control Methods

### 2.30.3.1 Measurement of Voltage

#### 2.30.3.1.1 Fundamentals

An ideal voltage-measuring instrument will determine the voltage between two points without drawing any current (since this could modify the measurement). In practice, all voltage-measuring instruments will draw a small amount of current, and this is usually defined in terms of the input impedance of the instrument. Many lower-cost multimeters will have an input impedance of 10 M $\Omega$ , and if such a meter is used to measure a voltage of 1 V, it will draw a current of 0.1  $\mu$ A. Whether or not this is acceptable will depend on the system being measured, but for many corrosion applications, the impedance would be too low, and a value of 1 G $\Omega$  or above is recommended (an even higher input impedance may be necessary for some systems, such as intact paint-coated metals or passive alloys).

A second consideration in the selection of voltage measurement instruments is the measurement quality required. There are several aspects to this, and we can define three terms with slightly different meaning:

- Resolution or precision is the ability to detect small changes in a large value (e.g., if the meter can measure a maximum of 1 V and can resolve 1 mV the resolution is one part in one thousand).
- Sensitivity is the ability to measure small values, irrespective of the range being used (it is relatively easy to measure changes of 1 mV in a signal with a maximum of 1 V, but it is much more difficult if the maximum is 1 kV).
- Accuracy is the ability to measure the 'true' value (this is often much less well-defined than resolution, as it depends on how well the instrument is maintained and calibrated as well as its initial specification).

An important aspect of voltage measuring devices is the speed with which they can adjust to and measure changes. For 'manual' instruments (i.e., instruments where the only output is viewing by a human, who

may or may not choose to write down the result), changes occurring over periods of less than a second cannot be resolved by the observer, and speed is a minor limitation. However, when the output is being recorded, whether by a computer or on a chart recorder, then the measurement speed is also important. For corrosion studies most information tends to be at rather low frequencies (rarely more than 1 kHz), although impedance measurements may go to higher frequencies.

#### 2.30.3.1.2 Single-ended and differential measurements

Voltage-measuring devices may have one input terminal connected to earth, known as a 'single-ended input,' or both input terminals may be independent of ground, known as a 'differential input.' In general, differential inputs are to be preferred, as they help to avoid problems associated with earth loops (see the following section).

#### 2.30.3.1.3 Instruments

A range of instruments is available to measure voltage:

- Moving coil meters are actuated by current but can be adapted to measure voltage by adjusting the resistance of the coil (plus a series resistor if necessary) to give an appropriate calibration. However, they generally have too low an impedance to be useful for corrosion measurements, and they have limited resolution (usually about 1% of full scale).
- Electronic voltmeters use a semiconductor circuit to amplify and convert the voltage to a suitable form for display, either on a moving coil meter or on a digital display (in which case the term digital voltmeter is normally used). Whichever form of display is used, the input impedance is a function of the amplifier used and can be very high (values of  $10^{14}$   $\Omega$  are commercially available, usually termed electrometers).
- Chart recorders provide a means of recording the variation of voltage with time. They are gradually becoming less widely used, both because they are relatively expensive, and, unlike computer-based data acquisition systems, the recorded data cannot easily be further processed. As with electronic voltmeters, the input impedance is a function of the electronics used, a value of 10 M $\Omega$  being common.
- Oscilloscopes can be thought of as specialized chart recorders that are optimized for viewing high-speed signals. Electrochemical measurements are only rarely concerned with high-speed measurements, and hence oscilloscopes are not widely used,

especially as their input impedance is usually rather low (1–10 M $\Omega$  being common). However, they can be useful for checking for high-frequency oscillation or viewing transient behavior (but note that modern computer-based data acquisition systems may provide similar or enhanced functionality for lower cost).

- Computer data-acquisition systems can be thought of as being similar to digital voltmeters, but with the display components being replaced by a connection to the computer, which can take over the display functions (as well as doing many other things). Unfortunately, the majority of computer data acquisition systems are optimized for rapid data acquisition ( $10^5$  or  $10^6$  samples per second being common), rather than high input impedance or high precision, and consequently they are not ideal for corrosion measurements.

#### **2.30.3.1.4 Earthing and shielding**

Induced interference is a common problem in electrical measurements. This arises because the signal circuits act as aerials for the pick-up of electromagnetic radiation. Much of this interference can be eliminated by appropriate earthing (also known as grounding) and screening of the signal circuits. An electrical earth (or ground) is a connection to a stable voltage at approximately the potential of the local soil. It is common to use the safety earth associated with mains power sockets to earth an appropriate part of the measuring circuit. In electrochemical measurements, it is common to earth the working electrode, although there may be circumstances in which this is not desirable. When configuring earth connections, it is very important to avoid an 'earth loop,' which involves two separate connections to earth. This results in a loop of wire, with earth forming part of the loop, and this loop can act as a very effective aerial for the pickup of mains frequency interference.

Interference pickup can be significantly reduced by screening the signal circuits. This involves surrounding the circuits with a metallic conductor that is connected to earth. Electromagnetic radiation cannot penetrate this conductor, and consequently cannot interact with circuits inside the screen. It is common to screen cables by using a coaxial cable, in which the inner conductor is screened by an outer braided screen, which is earthed (note that the comments above about earth loops also apply to the screen connection of coaxial cables). Larger circuits, such as electrochemical cells, can be enclosed in an earthed, conductive box, known as a Faraday cage.

### **2.30.3.2 Measurement of Current**

#### **2.30.3.2.1 Fundamentals**

An ideal ammeter will measure the current between the two input terminals while maintaining the voltage between the terminals at zero. In many modern instruments, current is measured by measuring the voltage across a resistor (known as a current shunt) that is inserted in the current path. This results in a small but significant voltage being developed (this is known as the 'voltage burden' and is typically of the order of 100 mV for a full-scale reading to allow the voltage to be measured with an acceptable accuracy), and such meters are unsuitable for many electrochemical measurements. The capabilities of an ammeter can be defined in terms of the input impedance (essentially the resistance across which the voltage is measured) and ideally we want the input impedance to be zero. An alternative current measurement method uses a form of amplifier known as a current amplifier (essentially an amplifier with a current input and a voltage output) that can measure current with a very low input impedance, and this is preferred for corrosion studies. In the corrosion field the term 'zero-resistance ammeter' is used to describe a current amplifier coupled with a suitable voltage measuring device.

### **2.30.4 Instruments**

Many current-measuring methods use similar instruments to those described earlier for voltage measurement. Such instruments normally use the method of measuring the voltage drop across a resistor to measure currents, but even if the instrument offers such a capability internally (as in the case of cheaper digital multimeters), it may be better to use it in voltage measurement mode with an external resistor, as this allows a greater control of the compromise between sensitivity and input impedance (i.e., a smaller resistor, and hence a smaller voltage, may be used, giving a less sensitive measurement, but one that is less affected by the input impedance of the measuring system).

There are three main classes of instrument that can measure current with negligible voltage drop. All of these use essentially the same current amplifier circuit, the only real difference being the packaging and primary function of the device:

- Electrometers normally include a very high input impedance voltage amplifier and a very low input impedance current amplifier capable of measuring

very small currents with a very low voltage burden (typically less than 1 mV).

- Zero-resistance ammeters are normally designed specifically to measure currents in the range of concern for electrochemistry.
- Potentiostats (see [Section 2.30.4.3](#)) can be configured to measure current with negligible voltage burden.

A limitation of all devices based on the current amplifier circuit is the limited maximum current that can be measured, as the full measured current must be supplied by an internal amplifier, and once the current exceeds the capability of the amplifier, the current amplifier will behave as a very high resistance.

### 2.30.4.1 Measurement of Resistance

#### 2.30.4.1.1 Fundamentals

In general, resistance is measured by applying a current to the circuit in question and measuring the voltage developed across it. Then the resistance is computed from Ohm's Law,  $V = IR$ , making the tacit assumption that the behavior of the component is correctly described by this law. Note that Ohm's Law does not apply to electrochemical interfaces, and somewhat more complex methods must be used.

#### 2.30.4.1.2 Instruments

Most digital multimeters can measure resistance, normally by applying a constant current, which will vary according to the resistance range selected, and measuring the voltage developed. This is generally satisfactory for larger resistances, but for accurate measurements, especially for small resistances, it is necessary to compensate for the resistance of the connecting cables. This is done using a 4-terminal measurement ([Figure 2](#)), in which the current is applied to the component using one set of cables, and the voltage is measured using a second set of cables. More sophisticated multimeters provide the separate current and voltage connections that are required for this method. When measuring

**Figure 2** Four-terminal method for resistance or impedance measurement.

the resistance of electrochemical interfaces, a variant of the 4-terminal measurement method must be used (see the discussion on the measurement of polarization resistance).

### 2.30.4.2 Measurement of Impedance

#### 2.30.4.2.1 Fundamentals

Impedance measurement can be seen as an extended form of resistance measurement in that a current is applied to the component in question and the resulting voltage is measured. In the case of impedance measurement, however, the current must be a sine wave and the voltage measurement must determine both the amplitude and the phase (with respect to the current) of the resulting voltage. In the general case, it is also necessary to vary the frequency of the sine wave and to account for nonlinearity and noise in the measurement. These aspects are discussed further in the following section.

### 2.30.4.3 Control of Potential – The Potentiostat

In the general case, the control of the potential of an electrode in an electrochemical cell can be achieved using a four terminal method that is similar to the 4-terminal method of measuring resistance, the current being supplied through one pair of connections and the voltage measured through a second pair. Then a control circuit can adjust the current to maintain a constant potential difference (or a potential difference that follows an independent control signal) between the two voltage measuring connections. However, one of the two connections (to the working electrode) is generally very low resistance and can use a single connecting wire in most cases, whereas the other (to the solution) has a high resistance (and other problems), and must use two connections, one for current (supplied to a separate conductor known as the counter electrode or secondary electrode or auxiliary electrode) and the other to measure the potential using a reference electrode. This leads to the three-terminal device (though it may have more connections to provide additional facilities) known as a potentiostat. In essence, a potentiostat is a very simple voltage amplifier that amplifies the difference between a control potential and the potential of the reference electrode by a very large amount and then applies it to the counter electrode (with the working electrode being connected to ground). Then if the control potential

differs from the reference electrode potential, the counter electrode potential will be changed in the opposite direction, tending to bring the reference electrode potential back to being the same as the control potential. This process is known as ‘negative feedback.’ A very basic potentiostat can be constructed for a few pounds (Steinberg and Lowe<sup>3</sup> provides an example circuit, although the method of current measurement is more complex than is necessary for most applications, and the circuit could be even simpler). Commercial potentiostats typically provide higher currents, better facilities for the measurement of current and potential, more controlled frequency response, etc.

#### 2.30.4.3.1 Operational amplifier model

The very simplest potentiostat can be constructed from a single operational amplifier (op-amp). (Nowadays the operational amplifier is a standard integrated circuit component that is available with a wide variety of specifications, costing less than £1 for lower specification devices.) The ideal op-amp is a device with three terminals (plus power supply connections – typical op-amp designs use power supplies with three outputs,  $-15$ ,  $0$ , and  $+15$  V, the  $0$  V output providing the reference for voltage measurements) as shown in Figure 3.

The relationship between the output of the amplifier ( $e_o$ ) and the noninverting ( $e_+$ ) and inverting ( $e_-$ ) inputs is given by

$$e_o = A(e_+ - e_-)$$

where  $A$ , the gain of the amplifier, is very large (typically of the order of  $10^6$  or more, although it falls with increasing frequency). For the ideal amplifier, the input impedance is infinite and therefore no

**Figure 3** Operational amplifier (power supply connections omitted for simplicity).

**Figure 4** Unity gain buffer.

current will flow into the inputs of the amplifier; for real amplifiers, it is normal to specify the input leakage current rather than the input impedance, and typical values range from  $100$  nA down to less than  $1$  pA, depending on the technology used to construct the amplifier.

#### 2.30.4.3.2 Principle of negative feedback

Most operational amplifier circuits rely on ‘negative feedback’ to provide the required function. In essence, this means that a signal derived from the amplifier output is fed back to the input such that the desired relationship between the input and the output is obtained.

The simplest negative feedback circuit is the unity gain buffer:

In this circuit, the input signal is connected to  $e_+$  and  $e_o$  is connected back to  $e_-$  (Figure 4). We can analyze the behavior by substituting for  $e_-$  in the op-amp gain equation:

$$e_o = A(e_+ - e_o)$$

Hence

$$e_o = e_+[A/(1 + A)]$$

As  $A$  is very large,  $[A/(1 + A)]$  is very close to  $1$ , so  $e_o \approx e_+$ .

By design, the input impedance of the operational amplifier is very large, and the output impedance is very low (and made lower still by the action of the negative feedback), thus providing an amplifier with a gain of one, very high input impedance and very low output impedance.

#### 2.30.4.3.3 Simple potentiostat circuit

The basic circuit to provide control of potential is also very simple (Figure 5).

Again, we can see how the circuit works by putting the various voltages into the gain equation for the op-amp (using  $V_{CE}$  for the potential at the counter electrode terminal and  $V_{RE}$  for the reference electrode,

**Figure 5** Operational amplifier circuit for potential control.

both relative to the working electrode, which is connected to the power supply ground):

$$V_{\text{CE}} = A(V_c - V_{\text{RE}})$$

Hence

$$V_{\text{RE}} = V_c - V_{\text{CE}}/A$$

As  $A$  is very large (usually  $> 10^6$ ), this implies that  $V_{\text{RE}} \approx V_c$ . As the electrode potential of the working electrode is measured relative to  $V_{\text{RE}}$ , this means that the potential of the sample will be  $-V_c$ .

Somewhat more detailed descriptions of potentiostat circuits are presented in **Chapter 1.02, Electrochemistry**. Note that the circuits for the unity gain buffer and the potentiostat illustrate a general fact for operational amplifier designs, namely that when operating with correct negative feedback, the voltage at the two input terminals is the same, that is,  $e_+ = e_-$ , and this provides a simple way of working out how the circuit will behave.

#### 2.30.4.3.4 Some potentiostat configurations

For simplicity, we shall draw the potentiostat as a box with three connections, labeled CE, RE, and WE (for Counter Electrode, Reference Electrode, and Working Electrode respectively), and a control input that permits control of the potential with an external input. Then the simplest potentiostat circuit controls potential, optionally following an external device, such as a sweep generator that provides a potential that varies with time (**Figure 6**).

The potentiostat may provide a means of monitoring the current, but if this is not available, then the current can be measured by inserting an ammeter in the lead from the potentiostat to the counter electrode or by inserting a resistor and measuring the voltage across it (note that the potentiostat automatically compensates for the voltage drop across the ammeter/resistor, and hence this is not a problem, providing it is not excessive; up to 1 V is reasonable).

#### 2.30.4.3.5 Control of current

If a potentiostat is configured to control the potential across a fixed resistor, this will produce a controlled

**Figure 6** Potentiostat used for control of potential.

current from the CE terminal to the RE terminal (**Figure 7**). It should be noted that in this circuit, the RE is at a voltage of  $V_c$  relative to instrument ground (the WE terminal), while the CE terminal is at whatever potential is necessary (within the capability of the potentiostat of course) to supply the current. (The term 'instrument ground' is used to refer to the 0 V connection of the power supply. This may or may not be connected to a true local ground (e.g., the earth pin of the mains connector).) It is often required to measure the potential that results from the application of a controlled current; note that the reference electrode must not be connected to the RE terminal to achieve this; some potentiostats may provide a mechanism for measuring the potential in galvanostatic mode (check the manual); alternatively an independent voltmeter must be used.

#### 2.30.4.3.6 Measurement of current

If a potentiostat is configured to control the potential between the RE and WE terminals at 0 V, then the current required to do this can be measured between the CE and RE terminals (**Figure 8**). The voltage burden is not particularly important, as the potentiostat will adjust the voltage at the CE terminal to supply the required current. An ammeter is shown in **Figure 8**, but this can, of course, be replaced by a resistor and voltmeter (providing the voltage across the resistor is within the capability of the potentiostat). Note that one current measuring connection is connected to instrument earth in this configuration, while the other (connected to the RE terminal) is a 'virtual earth' (i.e., it is at earth potential, but not actually connected to earth).

**Figure 7** Potentiostat configuration for current control.

**Figure 8** Configuration of potentiostat to measure current.

#### **2.30.4.3.7 Problems in potentiostatic measurements**

The potentiostat is a very useful device, but users should be aware of a number of possible problems:

- **Overloading**

The potential of the working electrode is controlled by current supplied from the amplifier in the potentiostat. The current and voltage available will be determined by the design of the amplifier and the power supply in the potentiostat. The voltage limit is very often  $\pm 15$  V, as this is the normal maximum supply voltage range for integrated circuit operational amplifiers (though higher voltage potentiostats are available). The current limit will vary from  $\pm 10$  mA for standard operational amplifiers, up to many amps for power devices. If the required potential demands more current or voltage than the potentiostat can supply, then the potential control will break down; this can usually be recognized by an unchanging current, corresponding to either the current limit of the potentiostat or the voltage limit in conjunction with the total circuit resistance.

- **Instability**

As already explained, the operation of the potentiostat depends on negative feedback. However, at higher frequencies, elements in the circuit (including the cable from the reference electrode to the potentiostat and circuits internal to the potentiostat) can introduce delays between a change in the potential being applied to counter electrode and the resultant potential appearing at the inverting amplifier input. At a frequency where the delay corresponds to half of the period of one cycle, the delay will convert negative feedback into positive feedback, which can result in strong oscillation of the potentiostat (this is essentially the same as the 'howl' when the microphone picks up the sound from the public address system). Very often the only measurements taken from a potentiostatic experiment are the potential and current – if these are made using dc instruments, the 'howl' will not be detected, and the potentiostat will just appear not to be working, as the dc value of the potential will typically not be what is intended. In this situation, it is important to check the current using an ac meter; alternatively check the cell voltage with an ac meter – do not try to measure the ac voltage between the reference electrode and the working electrode, as this will typically be very small (remember that it will be amplified by the

gain of the amplifier in the potentiostat before it is applied to the counter electrode). Such oscillations can usually be stopped (at the expense of slowing down the response of the potentiostat) by connecting a capacitor from the counter electrode terminal to the reference electrode terminal, which provides strong negative feedback at higher frequencies (1  $\mu$ F is usually sufficient). It may also be useful to reduce the effective impedance of the reference electrode at higher frequencies (especially when using high-resistivity solutions) by coupling it with a capacitor to a length of platinum wire wrapped around the tip of the Luggin probe (see [Section 2.30.8](#)).

- **Frequency response**

Many applications of potentiostats are concerned with 'near-dc' conditions, and the frequency response is not particularly important. For this reason and to avoid problems with instability, some potentiostats have a relatively low frequency response. Some applications, however, such as the measurement of electrochemical impedance or transient measurements with scratching electrodes, demand a response at high frequencies. Users should therefore take care to select an appropriate instrument for their application.

#### **2.30.4.4 Control of Current**

In principle, the control of current is simpler than the control of voltage, as we are not concerned with the source of any voltages developed in the external circuit. Thus, the simplest galvanostat is a two-terminal device, and many laboratory power supplies offer a controlled current mode of operation that may be suitable for some corrosion experiments (though they are typically not very easy to set accurately, especially for smaller currents). Alternatively, a potentiostat can be used very easily as a galvanostat by using it to control the voltage across a resistor ([Figure 7](#) and also in the Chapter **Electrochemistry** for an example circuit). Note that there can be earthing issues with galvanostats, as the simplest circuits (including potentiostats used as galvanostats) do not connect either of the output terminals to earth.

As with potentiostats, galvanostats have limits on the output current and voltage, but they are less susceptible to oscillation and similar problems (as the feedback is contained within the instrument, it is much easier to avoid the positive feedback that could give problems).

## 2.30.5 Electrochemical Methods

### 2.30.5.1 Potential Monitoring

The measurement of potential is very simple – a reference electrode is placed in the same solution as the working electrode and a voltmeter with suitable (high) input impedance is connected to measure the voltage difference between the two. Note that the negative terminal of the voltmeter should be connected to the reference electrode in order for the measured voltage to have the correct polarity. However, if the working electrode is connected to earth (as is quite likely in the case of plant measurements), this configuration may compromise the input impedance of the meter (since the negative input terminal of a voltmeter often has a much lower impedance to earth than the positive terminal), and in this case it is better to connect the meter ‘the wrong way round’ (i.e., connect the higher impedance positive terminal to the reference electrode) and reverse the sign of the measured potential.

Provided no current is being applied to the working electrode, it is not particularly important where the reference electrode is situated, and it is not necessary to use a Luggin probe (see [Section 2.30.8](#)). The only exception to this is for measurements of the distribution of potential over the surface of the sample, when the design and location of the reference electrode is critical.

While the measurement of potential is relatively easy, the interpretation may present problems. The corrosion potential is affected by many factors, and in the absence of additional information (such as a detailed understanding of the system in question), it is not possible to deduce anything about what is happening. As an example of a situation where the potential does provide useful information, the potential of carbon steel in concrete drops markedly when it starts to corrode, but even here, there is a wide range of potential over which the behavior is considered as uncertain, as indicated in [Table 2](#).

**Table 2** Determination of condition of steel in concrete from measured potential (from Tullmin *et al.*<sup>4</sup>)

Potential/V(CSE)	Condition
> -0.20	Passive
-0.20 to -0.35	Active or passive
< -0.35	Active (i.e., corroding)

### 2.30.5.2 Galvanic Current

As with the potential, the coupling current between two electrodes is relatively easy to measure, but more difficult to interpret. With a well-defined galvanic couple, the current may provide a useful indication of some feature of the environment, but it is difficult to be sure in the general case whether it will provide useful information and how to extract that information from the measured data.

Note that galvanic currents must be measured with a low potential drop, and therefore an electrometer, zero-resistance ammeter, or potentiostat should be used as described earlier.

### 2.30.5.3 Polarization Curves

#### 2.30.5.3.1 Introduction

One of the most common electrochemical methods in corrosion research and testing is the determination of the polarization curve – the relationship between the current and the potential, usually over a relatively wide range (of the order of a volt). It is normally the objective to determine polarization curves under near steady-state conditions (i.e., the measured current at each potential is essentially that that would be obtained after a long period at a constant potential). For at least two reasons, this is not really possible:

- When corrosion reactions are occurring, the electrode will change with time, especially in the anodic region of the curve, and hence there is really no such thing as steady-state.
- It is not usually feasible to use more than a few samples, and therefore measurements must be made at different potentials on the same sample; the prior history of the sample is thus likely to influence the behavior.

Thus, the measurement of a polarization curve involves an element of compromise, and the optimum method and parameters to use will depend on the system being studied. As a general rule, systems exhibiting a low corrosion rate benefit from slow measurement methods (since the electrodes will change only slowly by corrosion and the low currents involved will be more easily perturbed in the short term by factors such as double-layer charging currents and currents associated with thickening of passive oxide films), while systems exhibiting rapid corrosion can (and should) be measured more quickly, since the actively corroding surface will reach near-steady state quickly and will change more quickly as a result of corrosion.

### 2.30.5.3.2 Measurement methods

Polarization curves can be measured either by controlling the current and measuring the potential or by controlling the potential and measuring the current. Since control of current is somewhat easier than control of potential, early measurements tended to use controlled current, but it has a number of disadvantages; in particular, it is not possible to control the potential in the passive region of active-passive polarization curves using controlled current (Figure 9). Thus, modern approaches almost invariably use controlled potential.

The polarization curve is notionally a continuous function, in that the potential can be held at any value and the current measured. In practice, however, there are two approaches to the measurement – the potential can be swept smoothly through the range of values of interest (leading to a *potentiodynamic* polarization curve) or it can be stepped over a range of reasonably small steps (typically in the range of 10–50 mV and leading to a *potentiostep* curve). The advantage of the potentiodynamic method is that it provides an essentially continuous curve. The advantage of the potentiostep method is that the measured current can be taken at the end of the step hold period, and therefore it approaches steady-state a little more

**Figure 9** Potentiostatic and galvanostatic measurement of polarization curve (schematic). Note that there is only one current density for each potential, so potentiostatic measurement gives the complete curve. In contrast there are three possible potentials (only two of which are stable) corresponding to much of the range of current densities, so galvanostatic measurement cannot reach some parts of the curve, and flips from the active peak to transpassive corrosion on the positive-going scan direction, and from the passive current density to the active curve in the negative-going direction (denoted by the dashed arrows). Note also that it is impossible to hold the system in the passive region using galvanostatic polarization, as slight changes in condition will cause a transition to active corrosion.

closely for the same overall measurement time. It also permits the use of new specimens for each potential, which minimizes effect due to the prior history of the specimen (though it also much more time-consuming and expensive, and introduces questions about sample-to-sample reproducibility).

The potentiodynamic method requires a potentiostat, a linear sweep generator (to produce the potential sweep) and a recording device of some kind to record the current and potential. In principle, the latter can be an  $X$ - $Y$  recorder (possibly with a log converter on one axis to record  $\log(\text{current})$ ), or a conventional recorder with a hard-working research student to extract and process the information. However, most modern systems will use a computer data acquisition system to manage the measurement and facilitate the processing of the data. The wide dynamic range of the measured current presents something of a problem here, and it is common for dedicated systems to use automatic range switching in order to permit the measurement of both large and small currents.

The sweep rate is an important parameter, as it controls the closeness with which steady-state is approached. Typical values of sweep rate are of the order of  $1 \text{ mVs}^{-1}$ ; as indicated earlier, a slow sweep rate is required for low corrosion rates, while a faster sweep can be used (and may be necessary to avoid excessive modification of the working electrode by corrosion) for systems that are corroding rapidly.

### 2.30.5.3.3 Interpretation

The simplest approach to the interpretation of polarization curves is to model the curve as the summation of a series of curves corresponding to the individual electrochemical reactions that can occur. As activation-controlled reactions exhibit a linear relationship between potential and  $\log(\text{current density})$ , it is normal to plot potential using linear axes and current density using log axes (strictly the absolute value of current density, since  $\log(x)$  does not exist for  $x < 0$ ). Since the potential is usually the controlled variable and current density the measured variable, polarization curves should strictly be plotted with potential on the  $x$ -axis. However, early workers controlled current and therefore plotted current density on the  $x$ -axis, and many workers still use this convention.

**Figure 10** (taken from ASTM Standard G5:1998, which provides a standard method for determining polarization curves) shows an example polarization curve, in this case for a ferritic stainless steel in sulfuric acid (the curve displays as a band because

**Figure 10** Polarization curve for ferritic stainless steel in sulfuric acid (from ASTM standard<sup>5</sup>).

this figure shows the range of curves obtained by different labs on a particular batch of steel). The labels on the right of **Figure 10** indicate what is happening in each region of the curve. Note that there are two passivation reactions; the first corresponds to passivation by  $\text{Cr}_2\text{O}_3$ , while the second corresponds to passivation by  $\text{Fe}_2\text{O}_3$  as well as  $\text{Cr}_2\text{O}_3$ .

An important process in the analysis of polarization curves is the estimation of the Tafel slope (the slope of the linear region of the  $E-\log|i|$  curve). For an ideal activation controlled reaction, this is straightforward (though easy for beginners to miscalculate the slope, for example by taking  $\log(i_1-i_2)$  rather than  $\log(i_1)-\log(i_2)$ ). However, real polarization curves tend not to show a clear Tafel region, and it can be impossible to determine the Tafel slope. As a guide, a Tafel slope should be considered to be reliable only if it meets the following conditions:

- The polarization curve is straight for at least one decade of current (i.e., the current changes by a factor of ten).
- The straight region of the polarization curve should start at about one Tafel slope away from the open circuit potential (i.e., if the Tafel slope is

60 mV, then the curve should become linear at about 60 mV from the corrosion potential). This is not an exact rule, as it depends on the relationship between the anodic and cathodic slopes; if in doubt, a good check is to overlay the calculated curve onto the measured curve.

- The Tafel slope should not ‘undercut’ the polarization curve between the open circuit potential and the start of the Tafel region. If this occurs, it suggests that the Tafel slope corresponds to a different reaction from the one that is dominant at the open circuit potential; a common student error is to fit a Tafel slope to the hydrogen evolution reaction when the dominant reaction at the open circuit potential is oxygen reduction (**Figure 11**). The Tafel slope may be correct in this situation, but it is not relevant to the corrosion process (therefore, it cannot be used, for example, to compute the Stern–Geary coefficient).

#### 2.30.5.4 Linear Polarization Resistance

The linear polarization resistance is the slope of the  $E-i$  relationship at the open circuit potential (OCP) (i.e., at zero current), and it provides a method of

**Figure 11** Calculated polarization curve exhibiting ‘undercutting’ of cathodic Tafel region due to multiple cathodic reactions. This graph is based on the idealized behavior of iron in a neutral solution, where the primary cathodic reaction is oxygen reduction at the OCP, which gives rise to the ‘bump’ in the cathodic curve. Note that the anodic and cathodic Tafel slopes do not intersect at the corrosion potential, and the current density at the intersection is less than the corrosion current density (which is defined by the limiting current density for oxygen reduction, set to  $1 \text{ A m}^{-2}$  for this model).

estimating the instantaneous corrosion rate. It can be measured in a number of ways:

- The potential can be swept through a narrow range either side of the OCP, the current recorded, and the slope determined. This method is commonly used in laboratory measurements, as it has a number of advantages – the  $E-i$  plot produced provides an indication of measurement problems such as high noise levels (Figure 12), and it makes a true measurement of  $dE/di$  at  $i=0$ . However, it is relatively difficult to automate, as it is necessary both to compensate for changes in the OCP and to determine the slope of the curve at  $i=0$ .
- The current can be swept through a small range about zero and the potential measured. This has the advantage of automatically making a measurement that is centered on zero current, but the current range needs to be adjusted to compensate for changes in the measured resistance. This method also reveals measurement noise.
- The potential can be stepped between  $\text{OCP} - \Delta E/2$  and  $\text{OCP} + \Delta E/2$ , where  $\Delta E$  is a small potential difference (typically 10 to 20 mV). Then  $R_p$  can be determined as  $\Delta E/\Delta i$ , where  $\Delta i$  is the change in current density. This suffers from the difficulty of compensating for changes in the OCP, and errors can be introduced if the anodic and cathodic Tafel slopes are markedly different.
- An applied current can be stepped between  $-\Delta i/2$  and  $+\Delta i/2$  and the corresponding potential step,  $\Delta E$ , measured. This is the simplest approach for corrosion monitoring, as it automatically makes the measurement centered on the OCP, and the polarization resistance is directly proportional to  $\Delta E$  (since  $R_p = \Delta E/\Delta i$  and  $\Delta i$  is constant). The current amplitude should ideally be adjusted to keep  $\Delta E$  in a reasonable range, but this is not too problematic unless the corrosion rate varies over quite a wide range. This method is also subject to error if the anodic and cathodic Tafel slopes are markedly different.
- A more sophisticated approach to the measurement of polarization resistance is to apply a sine wave of current or potential and measure the amplitude of the potential or current respectively. Essentially, this consists in making a single frequency impedance measurement – see the following section for further information. This method has two main advantages: it is easier to account for extraneous noise, and the frequency at which the measurement is made is well-defined, which

**Figure 12** Linear polarization resistance measurement using a potential sweep and exhibiting measurement noise. In this case the amplitude of the noise is low enough that we can make a reasonable estimate of the polarization resistance.

facilitates interpretation. With the low cost of sophisticated electronics, this has become a good method for corrosion monitoring, especially as it can easily be combined with Harmonic Analysis for the estimation of the Stern–Geary coefficient (see [Section 2.30.5.6](#)).

In addition to the variety of methods of polarization that are available, polarization resistance can be measured either as the resistance between two equivalent electrodes (this has some practical advantages, notably the fact that the expected dc potential difference is zero) or as the resistance of a single electrode, using a reference electrode to connect to the solution in a reproducible fashion ([Figure 13](#)).

Note that the normal unit of  $R_p$  is  $\Omega\text{m}^2$ , that is, it is not, strictly speaking, a resistance, but a resistance times area.

A question for all of the measurement methods is the optimum cycle time for the measurement. The basic theory on which the polarization resistance method is based assumes that  $R_p$  is measured at a low frequency, such that capacitive and other time varying currents can be neglected. However, in some situations diffusion processes can change very slowly (notably in environments such as soil and concrete), and it is not feasible to measure  $R_p$  at sufficiently low frequencies. In this case it has been found that relatively fast

**Figure 13** Two- and three-electrode methods for polarization resistance and impedance measurement. Generic connections have been indicated on the measuring device – if a potentiostat is used for the measurement,  $I_+$  will correspond to the counter electrode terminal,  $V_+$  the reference electrode and  $V_-$  and  $I_-$  the working electrode (this will be one terminal unless the potentiostat has separate current and voltage measuring connections for the working electrode).

measurements (with a typical measurement cycle time of 30 s) still give good correlation with corrosion rate. This is attributable to the measurement of the charge transfer resistance with only a small contribution from the diffusional impedance (see Cottis and Turgoose<sup>6</sup> for further explanation), but note that this does lead to a  $B$ -value different than for very low frequency measurements.

#### 2.30.5.4.1 Interpretation

The interpretation of the polarization resistance is normally based on the Stern–Geary relationship:<sup>7</sup>

$$R_p = \frac{B}{i_{\text{corr}}}$$

where  $B$  is the Stern–Geary coefficient (it is often called the Stern–Geary constant, but it is not a true constant, being dependent on the metal and environment being studied), or simply the  $B$ -value; its unit is V.

Note that the  $B$ -value cannot be derived from the measured data (but see the sections on harmonic analysis and intermodulation distortion) and must be obtained from separate experiments, either by measuring the anodic and cathodic Tafel slope from a polarization curve or by using a practical calibration against corrosion rates measured by an alternative method, such as weight loss. In the absence of a suitable  $B$ -value, it is common to use 26 mV for activation controlled systems and 52 mV for systems with the cathodic reaction being limited by diffusion. These values correspond to typical Tafel slopes for these two cases, and the calculated corrosion rates will usually be within a factor of two or three of the true value, which is usually tolerable for corrosion monitoring, where the objective of the electrochemical corrosion monitoring is primarily to detect major changes in behavior.

#### 2.30.5.4.2 Errors

The polarization resistance method makes a number of assumptions about the system under investigation, and errors arise if these assumptions are invalid.

- It is assumed that there is only one anodic reaction (metal dissolution) and one cathodic reaction (oxygen reduction or hydrogen evolution). Note that this implies that the rates of the reverse reactions are negligible. This is not always valid: relatively noble metals such as copper and nickel may be close to equilibrium at their corrosion potential, and it is possible for  $R_p$  to be dominated by the metal–metal ion exchange reaction; similarly, the kinetics of hydrogen–hydrogen ion reaction typically control the potential of nickel–base alloys in hydrogen-containing high temperature water, and electrochemical measurements give little information about the corrosion reaction.
- It is assumed that both anodic and cathodic reactions obey Tafel’s Law, which implies that they must be under activation control. Truly diffusion limited reactions (i.e., reactions that are at the limiting current density) can also be regarded as

obeying Tafel’s Law, with a Tafel slope of infinity, but intermediate cases (where the current is at a significant fraction of the limiting current density) do not obey the Stern–Geary equation and will give errors. Similarly, passive alloys will have an anodic behavior that does not obey Tafel’s Law. Fortunately in the case of passive systems, the cathodic reaction will often obey Tafel’s Law, while the anodic reaction can be regarded as having a very high Tafel slope; consequently, they may obey the Stern–Geary relationship. This is not a major problem for corrosion monitoring, as the passive alloy will always have a high polarization resistance, and the exact corrosion rate is not usually of concern.

- The electrochemical reactions are uniformly distributed over the electrode (i.e., uniform corrosion is occurring). Polarization resistance measurements on electrode that are subject to localized corrosion are normally considered to estimate the average corrosion rate. This is justified if the corrosion process consists solely of a cathodic reaction (either obeying Tafel’s Law or fully diffusion controlled) on the passive surface and an anodic reaction at the localized corrosion site (e.g., within the pit or crevice) that obeys Tafel’s Law. However, this is not necessarily the case, and polarization resistance should be regarded as more of a qualitative measure if localized corrosion is occurring. Note that it is not possible to identify purely from the measured value whether or not the corrosion is localized or uniform.
- It is generally assumed that the relatively small current or potential perturbation that is applied as a result of the measurement of polarization resistance does not change the corrosion behavior. This is not necessarily correct, and the perturbation may change the behavior somewhat. This is more likely when using controlled potential methods, as these are more likely to apply a nonzero mean current to the electrodes.
- Polarization resistance measurements are necessarily performed on probe electrodes when used for corrosion monitoring. It is assumed that the probes have the same behavior as the plant, but there are several reasons why this may not be valid.<sup>8</sup>

#### 2.30.5.5 Electrochemical Impedance Spectroscopy

Electrochemical impedance spectroscopy, EIS, extends the polarization resistance method by measuring how the impedance varies with frequency. There are a

number of ways in which this measurement can be made (see Turgoose and Cottis<sup>9</sup> and Orazem and Tribollet<sup>10</sup> for further information on the technique), but in essence the measurement consists in applying a series of ac currents and measuring the ac potential response or applying a series of ac potentials and measuring the current response. The impedance is then calculated by dividing the potential by the current at each frequency (using complex arithmetic in order to maintain the phase information). There are a number of criteria that must be satisfied in order to make a valid measurement,<sup>11</sup> including:

- **Linearity:** the response of the system must be proportional to the perturbation (this is rarely true for electrochemical systems, but we approach it by using small amplitude perturbations).
- **Causality:** the response of the system must be a direct result of the perturbation (power line noise and similar interference would result in a breach of this requirement, as would randomly occurring currents associated with localized corrosion).
- **Stability:** this requirement requires that the system does not exhibit characteristics such as multiple values for a given perturbation, or (equivalently) regions of negative resistance (electrochemical systems are often not stable, including any systems that include an active–passive transition).

It is possible to test EIS data for failure to meet these requirements, the most common method being to use the Kramers–Kronig (K–K) transform; this allows for the calculation of the phase response from the amplitude response and vice versa. If the calculated and measured data do not match up, this implies that the data are not valid (note that this is a necessary, but not sufficient, condition – valid data will not fail the K–K transform test, but it is possible for invalid data to pass it).

#### 2.30.5.5.1 Presentation of EIS data

The EIS measurement produces a set of amplitude and phase values for a range of frequencies, and there are two main ways of presenting these:

- The Bode plot presents  $\log(\text{amplitude})$  and phase against  $\log(\text{frequency})$ . Figure 15 presents a Bode plot for the equivalent circuit of Figure 14 (this is known as the Randles equivalent circuit and has three components:  $R_s$  is the resistance of the solution,  $R_p$  is the polarization resistance of the metal–solution interface, and  $C_{dl}$  is the double-layer capacitance of the metal–solution interface).

On the Bode plot, a resistor produces a horizontal line on the amplitude plot with amplitude equal to the resistance and a constant phase of zero on the phase plot. A capacitor produces an amplitude that falls with a slope of  $-1$  as the frequency increases (the amplitude of the impedance is  $1/(2\pi fC)$ , where  $f$  is the frequency and  $C$  the capacitance), and a constant phase of  $-90^\circ$ ; as we are normally dealing with resistors and capacitors, it is common to invert the phase axis (i.e., plot  $-\text{phase}$ ) so that capacitive circuit elements give data above zero.

- The Nyquist plot normally plots the imaginary part of the impedance against the real part (Figure 16). The Nyquist plot invariably inverts the imaginary axis (i.e., it plots the imaginary component of impedance with increasingly negative values on the  $y$ -axis), so that capacitive circuit elements plot above the  $x$ -axis. One weakness of the Nyquist plot compared with the Bode plot is that it does not implicitly include the frequency of each measurement point, so at least some points should have their frequency indicated.

**Figure 14** The Randles equivalent circuit for a corroding interface.

**Figure 15** Example Bode plot for the equivalent circuit of Figure 14, with component values of  $R_s = 100\ \Omega$ ,  $R_p = 1000\ \Omega$ ,  $C_{dl} = 0.0001\ \text{F}$  (from Cottis<sup>8</sup>). Note that  $|Z|$  tends to  $R_s$  at high frequency and to  $R_s + R_p$  at low frequency.

**Figure 16** Example Nyquist plot (from Cottis<sup>8</sup>).

#### 2.30.5.5.2 Interpretation of EIS measurements

The interpretation of EIS data is essentially concerned with determining the components inside a sealed 'black box' with just two leads connected to the outside. It is relatively easy to determine the values of internal components if we know what their configuration is, but if we do not know the configuration or the number of components there is no unique solution to the problem, as there are an infinite number of circuits that could produce the observed behavior. The simplest example of this is circuits that contain only resistors. Any resistor network will appear from the outside as a pure resistor (i.e., the measured impedance will have constant amplitude and zero phase). Consequently, in order to obtain a valid interpretation, it is important to use prior knowledge of the expected behavior in order to model the real physical system.

There are two basic approaches to model EIS performance, and hence to determine the properties of the elements of the electrochemical interface by adjusting the parameters of the model to match the measured data:

- The response of the chemical and electrochemical processes to a fluctuating potential is analyzed with a mathematical or numerical model in order to produce a simulated spectrum, and the parameters of the model are adjusted to fit the measured spectrum. This is technically an ideal approach, as it provides a direct relationship between the physical processes occurring and the observed spectrum, and can include the effects of

nonlinearity in response, but it is very demanding of time and skill, and it is therefore used only infrequently.

- A much more common approach is for the components of the system under investigation to be modeled by electrical equivalent circuit elements that have similar characteristics to the actual processes concerned. Thus, a paint film can be modeled as a resistor (corresponding to ionic current passing through the film) in parallel with a capacitor (corresponding to the capacitance of the paint film acting as a parallel plate capacitor); underneath the paint film the metal–solution interface gives rise to a resistor (corresponding to the charge transfer resistance) in parallel with a capacitance (the double-layer capacitance). The response of the resultant electrical circuit is then modeled using conventional methods from electrical engineering, and the parameter values adjusted to optimize the fit between the model and real data. Note that the equivalent circuit is derived first, based on the physical processes occurring; it may then be necessary to modify the equivalent circuit to fit features of the measured data. It is important that the added elements are linked to a physical process; some less-experienced workers try different equivalent circuits to find the one that best fits the measured data and then try to work out what the elements correspond to; while this may provide a good fit to the data, the circuit may have the wrong configuration so that the values of circuit elements give no information about the real processes occurring.

#### 2.30.5.5.3 Advanced impedance measurements

Significant advances have been made in the EIS technique in recent years. These are largely related to the detection and handling of errors in the measurement and enhancing the speed of measurement.

In a conventional EIS measurement, the impedance is acquired sequentially at each of a set of frequencies. The frequencies are normally arranged as a geometric series (i.e., each frequency in the series is the product of the immediately preceding sample and a multiplier (the latter is typically chosen to give around seven frequencies per decade). With this analysis scheme, the time taken to determine a full spectrum is dominated by the lowest frequency included in the measurement. It is not uncommon for the lowest frequency to be 1 mHz, implying that the measurement of an impedance spectrum takes

several hours. Besides leading to long measurement times, this leads to questions about the stationarity of the system. Van Gheem *et al.*<sup>12,13</sup> have developed a measurement method that uses multiple simultaneous sine waves, permitting the simultaneous measurement of a full spectrum (the use of multiple sinewaves is not new; Van Gheem *et al.*'s method is novel in the way that it allocates measurement frequencies in such a way that the measurement of the power at frequencies that are not present in the applied signal permits the estimation of the impact of noise and nonlinearity on the measurement).

In a similar vein, Orazem<sup>14</sup> has developed a method to use the error structure of EIS data to optimize the fitting of equivalent circuit models to the data.

Unfortunately, the methods developed by Van Gheem and Orazem were not available in commercial EIS measurement systems at the time of writing, but they provide an important advance in the development of reliable EIS analysis methods.

### 2.30.5.6 Harmonic Analysis

Harmonic analysis may be thought of as a single-frequency impedance measurement that is extended to measure the first and second harmonics of the input signal.

When a sine wave voltage is applied to a linear system (see the definition of linearity given earlier), the resultant current consists only of a sine wave at the same frequency. However, if the system is nonlinear, as is the case with electrochemical interfaces, this produces some distortion of the sine wave, which creates harmonics of the input signal. Using similar assumptions to those used by Stern and Geary,<sup>7</sup> Dévay and Mészáros<sup>15,16</sup> showed that the amplitudes of the first and second harmonics can be used to determine the Tafel slopes of the anodic and cathodic reactions, and hence determine the  $B$ -value to be used in the estimation of  $i_{\text{corr}}$ . Thanks to the low cost and power of modern electronics, this approach has been adopted as a corrosion monitoring technique with the claimed advantage (based on the theoretical analysis, but not yet really validated in practice) that it does not depend on prior knowledge of the  $B$ -value.

In his analysis Mészáros showed that the double layer capacitance could be allowed for by taking measurements at two frequencies. However, this requires the assumption that the equivalent circuit is a simple Randles circuit, which is often not the case, and as far as the author is aware, all practical implementations of

this method depend on the measurement being made at a low frequency, such that the capacitive components of the equivalent circuit can be neglected.

### 2.30.5.7 Intermodulation Distortion

A further development of the harmonic analysis technique applies two sine waves to the corroding sample. These interact with the nonlinear interface to produce a rather more complex set of output frequencies (Figures 17 and 18). Besides the harmonics of the two input signals, intermodulation components are formed at the sum and difference frequencies. The method was first proposed by Mészáros and Dévay,<sup>17</sup> and the method was subsequently developed by Bosch *et al.*,<sup>18</sup> who termed it 'Electrochemical Frequency Modulation,' although the process by which the output signals are produced is termed 'intermodulation distortion' in the signal processing literature (and in Mészáros and Dévay's paper). (Intermodulation has been widely used in electronic systems for many years as a method for changing the frequency of a signal. Thus in a modern satellite TV system, the LNB (Low Noise Block downconverter) takes the microwave signal picked up by the satellite dish (with a frequency in the range 5–20 GHz) and mixes it through a nonlinear device with a locally generated signal to convert it to a lower frequency (which will be the difference between the incoming frequency and the local signal frequency) that can be handled more easily in the receiver itself, the original signals and all the other intermodulation components being removed by filtering.)

Analysis of the signals produced permits, in theory, the extraction of the Tafel slopes in much the same way as harmonic analysis, but in addition, certain pairs of frequencies can be shown to have constant ratios, and these have been proposed as a test of the reliability of the data (Bosch *et al.*, who first drew attention to these relationships, termed them 'causality factors' 2 and 3 on the basis that they should have values of 2 and 3 if the outputs are caused by the inputs, rather than being random noise). This is potentially a very attractive ability, but at the time of writing this method had been relatively little used, and it is unclear whether or not real systems follow the theoretical behavior well enough for the results to be relied upon.

The theoretical derivation of the analysis procedures for this method implicitly assumes that the measurement is made at a low enough frequency that capacitive effects can be ignored. The relevant

**Figure 17** Potential and current versus time for a simulated intermodulation measurement (controlled potential, cathodic Tafel slope 120 mV anodic slope 60 mV). Note the much lower amplitude of the cathodic currents as a result of the larger Tafel slope, and the resultant distortion of the signal compared to the input signal.

**Figure 18** Illustration of intermodulation distortion (the two input frequencies used were 0.002 and 0.005 Hz ( $f_1$  and  $f_2$ ); the signal at 0.003 and 0.007 Hz are the difference ( $f_2 - f_1$ ) and sum ( $f_2 + f_1$ ) signals; the signals at 0.004 and 0.01 Hz are the first harmonics of  $f_1$  and  $f_2$ ; the remaining signals result from intermodulation between  $f_1$ ,  $f_2$ , and harmonics and intermodulation components. The current was based on a 1 m<sup>2</sup> electrode, which is why the observed power spectral density is so high).

frequency is that of the highest component used in the analysis, and this typically requires the use of very low frequencies for the two input signals. It may be possible to analyze the phase and amplitude of the various output components in order to test for, and possibly to correct for, capacitive components, but this had not been done at the time of writing.

### 2.30.5.8 Transient Techniques

A number of transient techniques have been developed to probe the properties of electrochemical interfaces. Several of these are essentially attempting to determine the properties of elements of an assumed equivalent circuit. These have largely been superseded by EIS, since this obtains the same information in a more accurate and more general way. An example of such a technique is open circuit potential decay (OCPD). In this method, the metal–solution interface is charged by the application of a constant current until a steady potential is achieved. Then the current source is disconnected, and the potential allowed to decay back to its open circuit value, giving a potential–time curve similar to that shown in Figure 18.

Various methods can be used to interpret the resultant curve (see Bosch *et al.*<sup>18</sup> for details); most of these depend on the assumption that the interface can be described by a simple equivalent circuit and that the interface has been charged for long enough that the charging current into the double layer capacitance,  $C_{dl}$ , can be neglected.

### 2.30.5.9 Electrochemical Noise

Electrochemical noise (EN) can be defined as naturally occurring fluctuations in the current and/or potential of corroding electrodes.<sup>20</sup> Early workers regarded these fluctuations as merely a nuisance, to be removed by filtering or averaging if possible, but Iverson<sup>21</sup> realized that they may contain information about the rate and nature of the corrosion process. A number of techniques have been devised for the measurement of electrochemical noise,<sup>8</sup> but most measurements now determine the potential noise as either the fluctuation of the electrochemical potential relative to a low-noise reference electrode or the fluctuation of the potential between two nominally identical working electrodes, while the current noise is measured as the current between two nominally identical working electrodes. An extension of the method measures the potential and current noise

Figure 19 Typical OCPD plot (from Kelsall<sup>19</sup>).

simultaneously using three electrodes (Figure 19). This has a number of advantages, including the ability to determine the electrochemical noise resistance (see the following paragraph).

#### 2.30.5.9.1 Interpretation of electrochemical noise

Early work on electrochemical noise used largely heuristic methods to analyze the data, that is, a number of analysis procedures were tried, and the ones that seemed to work determined by experiment. More recently, more detailed theoretically-based analyses have been developed.<sup>19,22</sup>

One of the most useful parameters to come out of the early heuristic work was the electrochemical noise resistance,  $R_n$ . This can be defined as  $A\sigma_E/\sigma_I$ , where  $A$  is the area of each electrode and  $\sigma_E$  and  $\sigma_I$  are the standard deviations of current and potential respectively, assuming the conventional three-electrode configuration. (Throughout this chapter we take  $R_p$ ,  $R_n$ , and  $R_{ct}$  as being normalized to unit area (i.e., their unit is  $\text{Ohm m}^2$ .) This convention has not always been used (including by the author) and care should be taken to ensure that area effects are properly handled.) This result was first suggested by Dawson *et al.*<sup>23</sup> The result can be proved theoretically with relatively few assumptions:

- The current noise sources on the two working electrodes have the same mean and standard deviation and are uncorrelated.
- The measurements are made at a low enough frequency that capacitive and other effects can be ignored.

- The response of the two working electrodes to an applied current is defined by  $AR_p$ , where  $R_p$  is the polarization resistance.

With these assumptions, it can be shown that  $R_n = R_p$  (strictly we should say the expected value of  $R_n$  is  $R_p$ , since this is a statistical result that is only true on average). Thus,  $i_{\text{corr}}$  can be estimated as  $B/R_n$ , where  $B$  is the Stern–Geary coefficient.

The simplest theoretical analysis of the expected amplitude of the potential and current noise is based on the premise that the electrochemical process consists of a series of events that are characterized by a pulse of charge. At the lowest level, this pulse might be two electrons produced by the oxidation of one iron atom to  $\text{Fe}^{2+}$  or four electrons consumed by the reduction of one molecule of oxygen. (Note that corrosion texts often state that the anodic and cathodic processes associated with corrosion are tightly coupled, such that every oxygen molecule reduced requires two iron atoms to be dissolved. However, this is not strictly correct, and the coupling only occurs indirectly through the change in electrochemical potential that occurs as the double-layer capacitance is discharged. Thus the anodic and cathodic events are uncorrelated in the short term, and we can therefore treat them as independent noise sources.) Larger events would correspond to such processes as the anodic charge produced by the initiation, growth, and death of a metastable pit.

If we assume that individual events are uncorrelated (i.e., the occurrence of one event does not change the probability of a subsequent event occurring), we can use the shot noise analysis produced by Shottky<sup>24</sup> to describe noise production in thermionic valves. Individual events are treated as pulses of zero duration, but nonzero charge,  $q$ . Then if the mean current is  $I$ , the average number of events occurring each second is  $I/q$ . (Note that we use  $I$ ,  $I_n$ ,  $I_{\text{corr}}$ , etc. to indicate total current, rather than current density, because current noise is not expected to be proportional to specimen area, and therefore it is more meaningful to talk about the current for a given specimen area, rather than considering the current density.  $R_n$  on the other hand is expected to be inversely proportional to specimen area and it is therefore appropriate to normalize it to unit area (giving the unit of  $\Omega \text{ m}^2$ .) Analysis of the statistics of this process leads to the shot noise formula  $\overline{I_n^2} = 2qIb$ , where  $\overline{I_n^2}$  is the variance of the current noise signal and  $b$  the bandwidth of the measurement (the range of frequencies included in the measurement).

For a corroding electrode two processes must be occurring simultaneously (e.g., metal dissolution and oxygen reduction). In principle, we can estimate the noise due to each source and sum them to derive the total noise amplitude. However, it will commonly be the case that one of the processes produces significantly more noise than the other, in which case we only need to consider that process. Thus, for pitting corrosion driven by oxygen reduction, the pitting process is expected to produce much more noise than oxygen reduction under normal circumstances, and therefore, we can simply treat oxygen reduction as providing a constant current that brings the net current to zero. With this assumption, and assuming that we can apply the Stern–Geary equation to estimate  $I_{\text{corr}}$  from  $R_n$ , it can be shown<sup>19</sup> that we can estimate  $I_{\text{corr}}$ , the charge,  $q$ , in the transient events, and the frequency,  $f_n$  of those events:

$$\begin{aligned} I_{\text{corr}} &= \frac{B}{R_n} = \frac{B\sigma_I}{\sigma_E} \\ q &= \frac{\sigma_I\sigma_E}{Bb} \\ f_n &= \frac{I_{\text{corr}}}{q} = \frac{B^2b}{\sigma_E^2} \end{aligned}$$

where  $B$  is the Stern–Geary coefficient;  $\sigma_I$ , the standard deviation of current;  $\sigma_E$ , standard deviation of potential, and  $b$  is the bandwidth of measurement.

Note that these equations assume that only low frequencies are included in the calculation of standard deviation, and it is arguably better to use an estimate of the power spectral density (PSD) at a low frequency:

$$\begin{aligned} I_{\text{corr}} &= \frac{B}{R_n} = B\sqrt{\frac{\Psi_I}{\Psi_E}} \\ q &= \frac{\sqrt{\Psi_I\Psi_E}}{B} \\ f_n &= \frac{I_{\text{corr}}}{q} = \frac{B^2}{\Psi_E} \end{aligned}$$

where  $\Psi_I$  is the PSD of current and  $\Psi_E$  is the PSD of potential.

### 2.30.5.9.2 Measurement

Electrochemical noise is almost invariably measured as digitized time records. Thus, the measurement process consists of a number of steps, illustrated in [Figure 20](#). Potential noise typically has a low amplitude, and it is therefore common to amplify it – this is done as the first step in order to minimize the effects of other processes on the instrument noise. If the potential is measured with respect to a reference

**Figure 20** Three electrode EN measurement configuration.

electrode, it will typically have a relatively large dc value, and the voltage amplifier may also incorporate a dc offset to allow a larger gain to be used without exceeding the output voltage range of the amplifier.

Current noise is normally converted to a voltage signal using a current amplifier. It is not usually necessary to provide for a current offset as the current noise normally has an expected mean of zero.

Following amplification, the voltage and current noise signal should be filtered to remove unwanted frequency components (although the amplifier and filter circuits may be combined in a practical instrument). In particular, a low-pass antialiasing filter should be included to remove frequency components that could give rise to aliasing in the sampling process. A high-pass filter may also be incorporated to remove the dc level (as an alternative to the use of a fixed dc offset), although it is difficult to produce good analog filters with a very low frequency, and even good quality filters present ‘issues’ associated with the filter settling time when first switching on.

The continuous analog signal must then be sampled to convert it to a regular sequence of samples, and these sampled values must be converted from analog to digital values. These two processes may be combined if certain types of analog to digital convertor are used. Most electrochemical noise information is present at low frequencies (typically below about 10 Hz), and hence EN measurement systems do not have particularly stringent sampling rate requirements, and it is more important to have a high resolution. Most computer data acquisition systems are optimized for high-speed, relatively low-resolution sampling, and they are therefore unsuitable for EN measurements. Conventional digital

multimeters or electrometers usually provide more suitable measurement capabilities, and they may also provide some of the required signal conditioning (although for the best results separate signal conditioning systems are normally required).

Finally the sampled digital time series is either recorded for subsequent processing (this is typically done for research purposes) or processed online to produce summary parameters (typically used for corrosion monitoring).

The measurement of electrochemical noise requires care in order to avoid sources of noise other than true electrochemical noise. Some of the more likely sources of error are:

- **Instrument noise** – electrochemical noise often has a very low amplitude, and high-quality current and potential measuring systems are necessary in order to minimize the addition of electronic noise from the instrument. Instrument noise levels should be checked to ensure that the level of such noise is significantly below that of the measured signals. Instrument noise levels are influenced by the impedance of the system being measured, and a dummy cell with a similar impedance to that of the corroding system should be used in the calibration process (**Figure 21**, based on Ritter *et al.*<sup>25</sup>).
- **Quantization noise** – virtually all electrochemical noise analysis methods involve converting the analog noise signal to a sampled digital time record. If the resolution of the analog to digital convertor is inadequate, steps will be observed in the time record (**Figure 22**). These add a form of noise, known as quantization noise, to the data; providing the measured signal is changing sufficiently rapidly, the contribution of the quantization noise is to add white noise (noise with a constant PSD) to the signal. (If the signal is changing slowly compared with the quantization step size, the measured value may be constant for long periods, and in this case the effect of the quantization may be to reduce the apparent noise.)
- **Aliasing** – during the sampling process, signals with a frequency above half the sampling frequency are transformed into samples that appear to have a lower frequency (**Figure 23**). (Some digital-to-analog conversion methods reduce the sensitivity to aliasing by averaging the measured signal over the sample period. However, this does not completely prevent aliasing, and it is good practise to use antialiasing filters for all EN measurements.) It is important to use antialiasing filters to remove these frequencies

**Figure 21** EN Measurement System (ADC = Analog to Digital Converter) (from Cottis<sup>8</sup>).

**Figure 22** Dummy cell for determination of instrument noise levels (from Schottky<sup>24</sup>).

before sampling occurs, as it is impossible to distinguish the resultant sampled data from real low-frequency signals. It should also be appreciated that aliasing does not just occur within electronic devices; it can also be created in software. Thus, if the sampling frequency of a signal is reduced by decimation (selecting every  $n$ th sample), this will also produce aliasing, and a low-pass software filter should be applied to the original data before decimation. (As software filters can be constructed to have essentially ideal properties, this can be a useful approach. Indeed there are arguments that the most effective approach to the development of instrumentation for EN is to sample at a fixed, relatively high frequency and then deliver data at the required rate by filtering and decimation. Besides avoiding expensive, low-frequency analog filters, this tends to reduce the amplitude of quantization noise (this process is known as oversampling in the electronics literature).)

- Interference – electromagnetic interference from a number of sources may be picked up and amplified by the EN measurement system. This leads to two main types of error: mains frequency (power-line) noise (50 or 60 Hz depending on location) and relatively rapid transients

(duration of the order of ms) due to inductive effects associated with the switching of high currents (the laboratory refrigerator is a common source of the latter). While both of these types of interference can be identified relatively easily, it may be more difficult to do this once the data have been sampled. Thus, mains frequency noise will typically be aliased to a much lower frequency, and transients will appear to be at least one sample period long. Thus, it is always best to prevent such interference from getting into the measurement system. This is normally achieved by careful shielding and earthing.

### 2.30.6 Electrode Design

Specimens for corrosion electrochemistry can take many forms, and much will depend on factors such as the form in which the material is available, the objective of the measurement, and the type of corrosion behavior that is expected. Typical electrode constructions are shown in [Figure 24](#).

Factors that should be taken into account in the design of the electrode include:

- Surface to be studied  
Different planes in an alloy tend to behave differently as a result of segregation occurring during casting and subsequent thermo-mechanical treatment. Consequently, it may be important to study a particular surface, in which case only planar electrodes, [Figures 25\(b\), 25\(d\), 25\(e\), and 25\(f\)](#), are suitable ([Figure 25\(a\)](#) is not suitable, as the edges of the specimen are necessarily exposed as well as

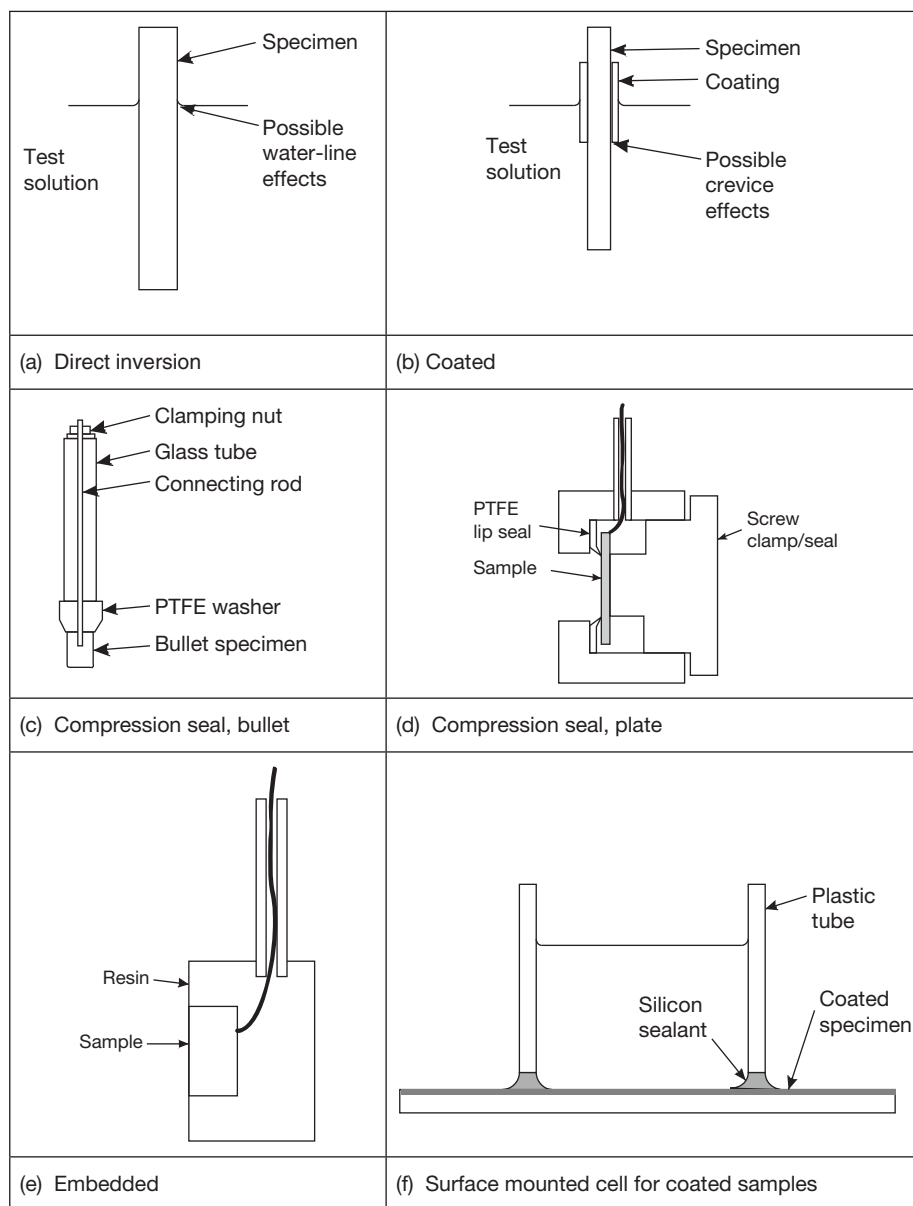

**Figure 23** EN time record showing quantization noise in the current signal (from Cottis<sup>8</sup>). The quantization can be seen as the 'banding' in the plot, illustrated by the two dotted lines superimposed on the plot at two adjacent quantization levels. This level of quantization is tolerable, and is not going to have a very large impact on the analysis.

**Figure 24** Illustration of aliasing (from Cottis<sup>8</sup>). Integrating sampling is used by many voltmeters, and averages the voltage over the sample period; instantaneous sampling just takes value of the voltage at the sample time, and is much more seriously affected by aliasing.

**Figure 25** Typical electrode designs for corrosion studies.

the surface of interest). Thought should also be given to the state of the surface (ground, polished, as received, etc.) as this can have a marked effect on the electrochemical behavior (the embedded electrode of [Figure 25\(e\)](#) is suitable for studying a specific plane, but not a preexisting surface, as the electrode preparation must include grinding and/or polishing of the embedded electrode to remove resin from the surface).

- **Susceptibility to crevice corrosion**

Passive alloys, including stainless steels, are susceptible to crevice corrosion. It is almost inevitable that electrode designs expose metal–insulator junctions to the test solution ([Figure 25\(a\)](#) is an exception, but it has its own problems associated with the waterline) and these are potential sites for crevice corrosion. Besides blatant damage to the specimen, this can lead to apparent passive current densities

that are much higher than the true values (Figure 26). A number of approaches have been used to minimize the risk of crevice corrosion:

1. The use of a PTFE-metal compression seal<sup>26</sup> can prevent crevice corrosion, but careful design and manufacture are necessary (PTFE-metal contacts have also been used as crevice-formers<sup>27</sup>).
2. Embedding a metal sample in epoxy or similar resin can lead to the formation of a crevice as the resin cracks away from the metal. The risk of this happening can be minimized by maximizing the adhesion of the resin to the metal by using an appropriate pretreatment (contact the resin manufacturer for advice), and by using a thin layer of resin (this minimizes the shrinkage stress between the resin and the metal; if a thick resin layer is required to facilitate surface preparation, this can be added as a second layer, when cracking will usually occur harmlessly between the two resin layers). Another
3. Some coatings are particularly liable to act as a crevice at the edge of the coating, while others, particularly those with a very good adhesion, may be less susceptible. Wax-based coatings may be useful, as the wax can usually be removed easily after the test.<sup>28</sup>
4. Crevice corrosion arises because of chemical changes (normally acidification) that occur in the crevice, and a method of avoiding crevice corrosion is to flush the crevice so that an aggressive solution cannot build up. (There are systems where the dominant factor involved in crevice corrosion is the potential drop down the crevice, but this is relatively unusual.) This is the basis of the Avesta Cell,<sup>29</sup> which uses a seal fabricated from filter paper that is flushed with distilled water.

**Figure 26** Effect of crevice corrosion on passive current density, revealed by the increase in passive current density (markers) compared to the standard curve (solid lines) (from Tullmin *et al.*<sup>4</sup>).

### 2.30.7 Cell Design

The design of cells for electrochemical corrosion measurements should take a number of factors into account:

- **Current distribution**  
In most cases, one objective for an electrochemical measurement will be to make the measurement at a uniform current density and potential over the surface of the specimen. In general, this is facilitated by ensuring a uniform current path between the WE and the CE (e.g., using by a cylindrical WE at the center of a cylindrical CE or by using two parallel plates). It is often suggested that the CE should be large compared with the WE, but this is not necessarily beneficial from the point of view of the current distribution. In general, it becomes more difficult to achieve a uniform current distribution as the solution conductivity decreases, since the IR drop will have a larger relative influence on the current distribution.
- **Mass transport**  
Besides the distribution of current, it is also important to consider mass transport effects, particularly when applying relatively large overpotentials, as in the case of the measurement of a polarization curve. If well-characterized flow conditions are required, a variety of configurations is available (see the Chapter on **Flow Assisted Corrosion** for further information). Where mass transport is less critical, stirring of the solution may be sufficient. Gas bubbling serves both to stir the solution and to control the gas concentration in the solution. Note that of the range of controlled flow configurations that are available, only a few offer mass transport conditions that are the same across the electrode, the rotating cylinder electrode probably being the best from this perspective.
- **Influence of reaction products**  
Any electrochemical reaction will induce a change in the local chemistry, and it is generally desirable to minimize the influence of such changes on the measurement. The nature and significance of such changes will vary according to the system under study, concentrated solutions typically being less seriously affected than dilute solutions. The local concentration at the metal surface will be influenced by mass transport, while the bulk concentration will be influenced by the solution volume and the applied current. The reaction products at the counter electrode should also be considered, and

in critical cases, it may be necessary to separate the working electrode and the counter electrode compartments.

- **Control of gas composition of solution**  
Dissolved gases, notably oxygen, can be very important in corrosion reactions, and it is important to control the gas concentration of the solution. For aerated solutions this can be simply achieved by bubbling air through the solution. Deaeration is much more difficult, both because commercial gases typically contain traces of oxygen and because oxygen diffuses very rapidly (it even diffuses relatively rapidly through many polymers). Consequently, for rigorous deaeration, it is necessary to take great care to prevent oxygen access (e.g., by sealing the cell, bubbling the exhaust gas from the cell through water to restrict back diffusion, and possibly by purging the gas used to deaerate the solution by passing it through a suitable solution such as vanadous chloride). Any gases produced at the counter electrode must also be considered, as noted earlier.
- **Temperature**  
Chemical and electrochemical processes are generally rather sensitive to temperature (for typical activation energies corrosion rates double every 10 °C). Consequently for accurate measurements, the temperature should be controlled (or at least recorded). Temperature control is easier when the temperature is above ambient, and it is usual to perform tests somewhat above room temperature (e.g., at 30 °C). Tests at temperatures approaching boiling point become difficult, with respect to the maintenance of the solution composition (especially for dissolved gases) and because condensed moisture from the test can cause electrical leakage problems. For tests at above ambient pressure, it is necessary to use an autoclave, and electrochemical measurements become far more difficult and are beyond the scope of this article.

### 2.30.8 Reference Electrode

A range of reference electrodes is available (see [Table 3](#) and the Chapter **Electrochemistry**).

Note that the solution in the reference electrode plays an important part in controlling the potential of the electrode. Thus, a saturated calomel electrode must have saturated KCl as the solution in contact with the Hg/Hg<sub>2</sub>Cl<sub>2</sub> paste. This means that the SCE

**Table 3** Common reference electrodes

Common Name	Electrode	V vs NHE	Notes
Saturated* Calomel Electrode (SCE)	Hg/Hg <sub>2</sub> Cl <sub>2</sub> /sat. KCl	+0.241	Probably the most common electrode in the laboratory, but use of mercury presents safety hazards
Calomel	Hg/Hg <sub>2</sub> Cl <sub>2</sub> /1 M KCl	+0.280	Better temperature stability than SCE
Mercurous sulfate	Hg/Hg <sub>2</sub> SO <sub>4</sub> /sat. K <sub>2</sub> SO <sub>4</sub>	+0.640	Useful for avoiding Cl <sup>-</sup> contamination of test solution
	Hg/Hg <sub>2</sub> SO <sub>4</sub> /0.5M H <sub>2</sub> SO <sub>4</sub>	+0.680	
Mercurous oxide	Hg/HgO/1M NaOH	+0.098	Good for alkaline solutions
Silver chloride	Ag/AgCl/sat. KCl	+0.197	Very easy to make, but light sensitive, tending to replace SCE as most commonly used
Copper sulfate	Cu/sat. CuSO <sub>4</sub>	+0.316	Robust, commonly used for cathodic protection in soils (best avoided in chlorides because of precipitation of CuCl <sub>2</sub> )
Zinc/seawater	Zn/seawater	-0.8	Not a true reference electrode, but robust and quite stable

\*Note that the S in SCE stands for Saturated (not Standard) owing to the use of a saturated solution of KCl.

tends to leach chloride (and potassium of course, although this is usually less significant for corrosion) into the solution in contact with it. This leaching will contaminate the solution in contact with the reference electrode. Whether or not this leads to a serious problem depends on the test solution and the configuration of the reference electrode. In general, it is beneficial to use reference electrodes based on anions that are already present in the test solution. Thus, SCE is fine for seawater and other solutions containing high concentrations of chloride, but would be undesirable in chloride-free solutions.

It is a general objective of electrochemical measurements to measure the potential of the working electrode relative to the solution immediately adjacent to it. If there is no current applied to the working electrode, then this is not a problem, as there will not normally be significant currents in the test solution, and hence the potential will be essentially constant throughout the solution. However, when the working electrode is polarized, there will be potential drops in the solution (commonly called 'IR-drops') due to the interaction of the applied current and the resistance of the solution. There are several approaches to minimizing or correcting for the IR-drop:

- The reference electrode can be placed close to the surface of the working electrode. In practice this is usually undesirable due to the relatively large size of most reference electrodes (although micro electrodes are available) and the contamination of the working electrode by species leaching from the reference electrode. A way around both of these problems is the use of a Haber–Luggin probe (also

known as a Luggin probe), which is an electrically insulating tube with a fine tip that is placed close to the surface of the working electrode. The other end of the tube is connected to an electrode holder into which the reference electrode is inserted, and the tube and electrode holder are filled with the test solution. (A tube filled with solution is known as a 'salt bridge' and is essentially the ionic conduction equivalent of an insulated metal wire (although the resistance is, of course, much higher).) This provides a small probe that can be placed close to the surface of the working electrode (but not too close, about 3 tip diameters is generally recommended to avoid shielding part of the surface), and it also reduces the significance of leaching of the reference electrode solution into the test solution.

- The potential drop can be compensated for in one of a number of ways. The simplest method is to correct the measured potential based on an estimate of the solution resistance, but this may have undesirable consequences for some measurements, such as the measurement of polarization curves, where the effective sweep rate may be very different from that intended as a result of changes in the IR-drop during the measurement. Alternatively the estimated resistance can be used by the potentiostat to compensate for the IR drop. In essence, the applied current is passed through a resistor with the same value as the estimated solution resistance, and the resultant voltage is added to the control voltage. This is a form of positive feedback, and will result in instability in the potentiostat if the estimated resistance is too large; consequently, it is difficult to compensate completely

for the IR-drop. Another approach is to use the fact that the metal–solution potential tends to decay relatively slowly when the current is disconnected (due to the effect of the double-layer capacitance), whereas the IR-drop disappears essentially instantaneously. This leads to the current-interruption method, whereby the true potential is estimated when the current is briefly switched off.

### 2.30.9 Counter Electrode

In some cases, typically when working with micro-electrodes, or when the current is very small for some other reason, it is possible to use the reference electrode as the counter electrode. The use of a specific counter electrode can also be avoided by using two working electrodes, and this may be useful in the measurement of polarization resistance or electrochemical impedance (seen already). In all other cases where current is applied to the working electrode, a counter electrode is required as the second connection to the test solution.

In most cases, the counter electrode should not affect the measurement, and it should therefore have the following properties:

- It should have a relatively low polarization resistance so that the potential drop between the counter electrode and the solution does not limit the polarization that can be applied.
- It should not contaminate the solution. In practice, there will always be some electrochemical reaction at the counter electrode, and what we really need is for the products of that reaction to be harmless or easily removed. Inert electrodes, such as platinum or graphite are often used, in which case the reaction products are usually gases (oxygen or chlorine when anodic or hydrogen when cathodic) that can be removed by bubbling air or nitrogen past the counter electrode (although there may also be a pH change at the counter electrode). In closed systems (e.g., in autoclave studies), it is more difficult to dispose of gaseous reaction products, and it may be better to use a reactive electrode and trap the reaction products close to the counter electrode (e.g., by using an ion-exchange membrane between the counter electrode and the working electrode). It is also wise to check that supposedly inert electrodes are actually inert – some platinum dissolution can occur at high enough anodic current densities and graphite electrodes tend to release

traces of impurities into the solution as the graphite is oxidized to CO<sub>2</sub>. Note that many metals, including carbon steels and stainless steels, are essentially inert when cathodically polarized, and they can therefore be used as counter electrodes when only anodic polarization of the working electrode is required (e.g., when studying pitting breakdown potentials of stainless steel).

- It is often stated that the area of the counter electrode should be large compared with the working electrode, but this may be less important than ensuring that the overall cell configuration provides the required current density distribution. Thus, a counter electrode of the same size as the working electrode, mounted parallel to it, may optimize the current distribution without significant adverse effects from the size of the counter electrode.

 **$F_{hkl}$**  Structure factor  
 **$f_n$**  Atomic form factor  
 **$h$**  Planck's constant

$h\nu$	Photon energy
$I$	Intensity of radiation
$m$	Mass of projectile ions in ISS, MEIS, RBS
$M$	Mass of a target atom
$n$	Complex index of refraction
$Q$	Reciprocal lattice vector
$Q_z$	Transferred momentum
$R_n$	Lattice vector of atom $n$ in real space
$T$	Spectrometer transmission function
$\beta$	Imaginary part of the refractive index
$\delta$	Real part of the refractive index
$\Delta\theta$	Width of a diffraction peak
$\phi$	Incidence angle
$\phi_c$	Critical angle of total reflection
$\lambda$	Wavelength (X-ray, photon, photoelectron)
$\Lambda$	Photoelectron mean free path
$\mu$	Absorption coefficient
$\Theta$	Scattering angle in RBS, ISS, Bragg angle in a diffraction experiment
$\sigma$	Photoionization cross section
$\omega$	Angle of acceptance of an analyzer

### 2.31.1 Introduction

Corrosion is the attack of solid material by the environment, which could be liquid or gas phase. The pertinent reactions involve oxidation or reduction of the material's surface which yield products that are transferred, at least temporarily, into the surrounding phase, that is, species into the gas phase, species dissolved into the electrolyte, or deposits on the surface. Corrosion studies usually involve weight loss or weight gain measurements, electrochemical studies, and the analysis of the electrolyte and the solid surface with spectroscopic methods. Most of these investigations start with assumptions about a corrosion process and its chemistry. The analysis of the data may be very accurate and sensitive like in the case of electrochemical methods. However, the nature of the process itself often remains uncertain. Thermodynamic data provide a reasonable basis for assumptions of the processes occurring at the surface, which may be deduced from potential–pH diagrams, the so-called Pourbaix diagrams.<sup>1</sup> They give the first insight into the most likely chemical and electrochemical processes, but they are uncertain because they are based on pure equilibrium data and thus do not account for the kinetic characteristics of the system which may dominate the process. As a result, any study on the basis of electrochemical and other

physicochemical data requires the application of surface analytical methods to learn about the nature of the chemical processes which then may be used for their interpretation. Besides the knowledge of the chemical processes, one needs information on the structure of the surface and of surface compounds and their changes which may significantly influence surface reactions. Similar to the information on the surface and the surface compounds, one needs knowledge of the chemistry and the structure of soluble or gaseous corrosion products, which may be obtained by appropriate methods such as rotating ring disc studies or spectroscopic investigation of the electrolyte or the gas phase.

Spectroscopic methods, which are sensitive to the surface chemistry and structure, may be applied *ex situ* and/or *in situ*. Although *in situ* methods are often preferred because they allow one to follow the surface reaction in its natural environment, several *ex situ* methods give such rich and detailed chemical and structural information that they are widely used and well accepted for the interpretation of a corroding system. Of course, one has to be sure that the transfer of the specimen from its environment to the spectrometer does not introduce changes, which then are studied and lead to misinterpretation. The loss of contact with an aggressive atmosphere or an electrolyte solution, the loss of potential control after electrochemical treatment and sample transfer to a vacuum, which is necessary for several methods, should not introduce artifacts to the composition and structure of the specimen's surface. Experience to date indicates that there are methods and equipments that largely meet these requirements.

All spectroscopic methods involve excitation of the solid surface or the homogeneous medium in front (gas or liquid phase) which then induces a response from the system under study. Exciting radiation may consist of electrons, atoms, ions or electromagnetic radiation from the infrared (IR) to the hard X-ray range. Emission of electrons, ions, molecules, or electromagnetic radiation is the response. This chapter intends to give a brief summary of important spectroscopic methods which have been applied successfully to corrosion research and to the solution of practical corrosion problems. The principle, the strength, and the limits of these methods will be discussed and an example in each case will illustrate their application. **Table 1** presents a summary and a comparison of the various techniques. A more detailed description of surface analytical methods and their application to corrosion are discussed elsewhere.<sup>2,3</sup>

**Table 1** Characteristics of some surface analytical methods for corrosion in research and practice

<i>Method</i>	<i>Depth resolution</i>	<i>Lateral resolution</i>	<i>Information</i>
XPS (X-ray photoelectron spectroscopy)	2 nm	100 nm	Composition of surface and surface films, binding, and oxidation state, <i>ex situ</i>
UPS (UV photoelectron spectroscopy)	1 nm	>1 nm	Work function, threshold energies, band structure, and binding orbitals, <i>ex situ</i>
AES, SAES ([scanning] auger electron spectroscopy)	2 nm	20 nm	Composition of surface and surface films, and high lateral resolution, <i>ex situ</i>
ISS (ion scattering spectroscopy)	0.3 nm	20 nm	Composition of surface and surface films, modest lateral information, and high depth resolution (monolayer), <i>ex situ</i>
RBS (Rutherford back scattering)	5 nm	0.1 mm	Quantitative quasi-nondestructive depth profile, thick films, modest depth resolution, <i>ex situ</i>
SEM (scanning electron microscopy)	2 nm	1 nm	Surface topography with high lateral resolution, <i>ex situ</i>
EMA (electron microprobe analysis)	2 $\mu$ m	2 $\mu$ m	Composition of surfaces and surface layers, <i>ex situ</i>
SIMS (secondary ion mass spectroscopy), TOF SIMS	0.5 nm	20 nm	Composition of surfaces and surface layers, high sensitivity and mass resolution, isotopes, large molecules detection, <i>ex situ</i>
X-ray reflectivity	0.1 nm	>1 mm	Surface roughness, <i>in situ</i>
XRD (X-ray diffraction)	2–3 nm	100 nm	Atomic structure, (micro) crystalline materials (>3 nm), surface sensitive for grazing incidence, <i>in situ</i>
XAS (X-ray absorption spectroscopy)	2–3 nm	100 nm	Near range order also of amorphous structures by EXAFS, analysis of electrode surfaces and electrolyte films, chemical information by XANES, <i>in situ</i>
GDOES (glow discharge optical emission spectroscopy)	~1 nm	1 mm	Fast elemental analysis of surfaces and thin layer depth profiling, <i>ex situ</i>
IR (infrared spectroscopy), ATR (attenuated total reflection) IR spectroscopy, and IRAS or IRRAS (IR reflection absorption spectroscopy)	~0.5 nm	10 $\mu$ m	Chemical information via oscillation modes of adsorbates and thin layers, <i>in situ</i> by grazing incidence or total reflection from the rear side of thin vapor deposited films despite water absorption

### 2.31.2 Methods Working in the Vacuum and Sample Transfer

Many valuable spectroscopic methods function only in vacuum, for example, X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), secondary ion mass spectroscopy (SIMS), ion scattering spectroscopy (ISS) for low energy ions (1–5 keV) or high energy ions, and Rutherford backscattering (RBS). Indeed, typically, the evaluation of energy and mass of emitted electrons and ions requires ultra-high vacuum (UHV) conditions. There has been a strong debate on the usefulness of these methods, with their application in corrosion research being compared to experiments in surface physics. In physics, mostly single crystals were investigated, and the UHV equipment was not flexible enough for a rapid

specimen exchange. However, since the mid-1970s, when spectrometers were equipped with effective sample transfer systems, these methods have been applied very successfully to studies in surface chemistry, corrosion science, catalysis, and practical surface problems in industry. Any kind of surface, such as metals, semiconductors, insulators, and polymers may be studied as long as it is stable under vacuum conditions and does not contaminate the spectrometer. The wide application of these methods in various fields has shown that the achieved data are extremely useful, and one almost cannot avoid his or her use for the solution of many problems in research and industry. However, one has to keep in mind that they require sample transfer to UHV, and as a result, the specimen loses contact with a gaseous environment or the electrolyte and potential control during

sample transfer. Furthermore, exposure to the laboratory atmosphere may cause contamination of the surface and oxidation of surface compounds and corrosion products. In addition to this, the structure of the surface and surface layers may change due to dehydration and oxidation. These problems may be minimized or avoided in corrosion research by an electrochemical specimen preparation within a closed system and its transfer via a protecting inert gas atmosphere.

Several systems have been described in the literature with a shuttle taking specimens from the preparation stage to the UHV environment of the spectrometer, or a specimen preparation facility within a special vessel attached to the spectrometer and an appropriate transfer system to the analyzer chamber.<sup>4,5</sup> Figure 1 presents an example of the equipment that has been used successfully for corrosion research and the investigation of passive layers in the laboratory of the authors during the last 25 years. In addition to the three chambers of a commercial spectrometer, the analyzer chamber, preparation chamber, and the fast entry lock, an electrochemical preparation chamber is attached which contains a small electrochemical vessel of  $\sim 3\text{ cm}^3$  volume for electrochemical specimen preparation under well controlled conditions and under the protection of a purified argon atmosphere.<sup>4,5</sup> Water and the electrolyte are degassed by purified argon and are introduced from the containers to the electrochemical vessel, which is equipped with a counter electrode and the reference electrode. The specimen is contacted to the electrolyte surface using a hanging meniscus geometry. Pulse programs given to the

potentiostat allow a specimen preparation at the potential of choice in the range of milliseconds or less up to hours. A typical specimen preparation starts with cleaning by argon ion sputtering within the preparation chamber. Then the sample is transferred to the electrochemical chamber and contacted to the electrolyte at sufficiently negative potentials so that one starts with an oxide free clean surface. The potential is then pulsed to a value of interest and then returned to a value where the sample is not expected to change further. Finally, it is washed with degassed water and transferred to the analyzer chamber for its surface analytical investigation. This system has been applied to many studies of corrosion and passivity. It is even suited for the study of the electrochemical double layer by XPS when the electrode can be removed from the electrolyte under water repelling (i.e., hydrophobic) conditions.<sup>4,7</sup> In this case, the surface is not washed by water after its preparation. For these studies, one may follow with XPS, both qualitatively and quantitatively, changes in the chemical composition of the double layer with the electrode potential and may also investigate the changes in the energy of XPS features with the potential, which is related to the position of the species within the double layer.<sup>8</sup> The system also contains an additional port on the fast entry lock to allow for introduction from a transfer vessel of samples which have been prepared within a glove box or in an *ex situ* experimental stage, enabling exposure to aggressive gases, such as HCl. Together with a shuttle, the spectrometer has been applied successfully for high temperature corrosion research in aggressive gas phases.<sup>9</sup>

**Figure 1** Schematic representation of a commercial XPS Spectrometer with three vacuum chambers, and an attached electrochemical chamber with an electrochemical vessel. A rack and pinion drive system permits a fast and flexible specimen transfer.<sup>4-6</sup>

### 2.31.3 X-ray Photoelectron Spectroscopy

XPS is a widely used soft surface analytical method, which usually does not introduce changes due to the analysis itself. An XP-spectrometer consists of an X-ray source, an energy analyzer, and a detector. A monochromatic X-ray beam leaves the X-ray source, strikes the specimen surface, and ejects electrons. Typically, a twin anode X-ray source is used, providing either Mg  $K_{\alpha}$  ( $E = 1253.6 \text{ eV}$ ) or Al  $K_{\alpha}$  ( $E = 1486.6 \text{ eV}$ ) radiation. The kinetic energy of the photoelectrons is measured by an electrostatic energy analyzer. Modern spectrometers use a spherical or a spherical sector analyzer and an electrostatic lens focusing the electrons to its entrance slit (see [Figure 2](#)). The standard detector is a channeltron, an electron multiplier of special design with a potential drop of 3–4 keV across its surface. In most cases, an array of several channeltrons is used, or a channel plate with a two-dimensional arrangement of many small channeltrons on a plate to increase the sensitivity. The spectral data emerging from the channeltrons are sorted out with respect to their energy and added to each other appropriately with the help of the computer. The analyzer consists of a spherical

condenser supplied with a voltage which allows electrons with the appropriate pass energy to travel through it via its entrance and exit slits. It may be seen as a band pass filter which permits the transfer of only those electrons with the correct energy, the so-called pass energy  $E_{\text{pass}}$ . A linearly changing retardation voltage between the specimen, usually at ground, and the entrance slit is applied, so that all electrons have the chance to get successively through the analyzer when a spectrum is taken. Due to the specific energetic situation between the specimen and the analyzer, the energy balance of the photoelectrons follows [eqn \[1\]](#).

$$h\nu = E_B + E_{\text{kin}} + e\Phi_A \quad [1]$$

The energy  $h\nu$  of an absorbed X-ray photon is used to ionize an electron with binding energy  $E_B$  from an atom at the surface. For solid specimens,  $E_B$  is measured relative to the Fermi level  $E_F$ . Any excess  $h\nu$  energy, beyond that required for ejection, provides the electron with its kinetic energy  $E_{\text{kin}}$ , which is measured relative to the energy analyzer. [Figure 3\(a\)](#) illustrates the energy balance of the photoelectron of [eqn \[1\]](#). It contains the work function  $e\Phi_A$  of the analyzer, which is a constant of the spectrometer that is compensated internally after its calibration. With all

**Figure 3** (a) Energy diagram for XPS showing the potential wells of the specimen and the analyzer along with electronic levels, Fermi energy  $E_F$ , the related work functions  $e\phi_S$  and  $e\phi_A$ , contact potentials difference  $\phi_A - \phi_S$ , and the related kinetic energies  $E_{kin,S}$  and  $E_{kin,A}$ . A contact situation between analyzer and the specimen is shown with equal Fermi energies  $E_F$ .<sup>10</sup> (b) Mechanism of XPS with exciting X-rays of energy  $h\nu$  and electrons emitted from a core level (a) and from the conduction band (b) with initial energies  $E_i$  and final state energies of  $E_f$ . The resulting XP-spectrum is displayed, indicating the binding energy  $E_B$  and kinetic energy  $E_{kin}$  of the photoelectrons. For simplicity, the contact potential difference of the specimen and the analyzer as well as the retardation voltage are omitted.<sup>10</sup>

other quantities known,  $E_B$  is given by eqn [1]. Usually, a spectrometer is calibrated relative to the XPS-signals of well characterized standards mostly of pure metals such as  $E_B$  ( $\text{Au}4f_{7/2}$ ) = 84.00 eV,  $E_B$  ( $\text{Ag}3d_{5/3}$ ) = 368.26 eV,  $E_B$  ( $\text{Cu}2p_{3/2}$ ) = 932.67 eV.

In most cases, a spectrum contains several XP signals from each of the elements at the surface of a specimen due to their characteristic electronic levels, as indicated in Figure 3(b). It also contains X-ray induced Auger features, which arise through filling of the ejected photoelectron's core hole with an electron

from a higher energy level. As shown in Figure 4, the excess energy resulting from this transition may lead to the ejection of a third electron, the Auger electron. Another competing process is the emission of a photon, that is, X-ray fluorescence. Heavier elements ( $Z > 35$ ) have a high Auger yield so that their XPS spectra contain strong Auger lines.

The energy resolution of the XP-spectra is limited by the width of the excitation lines, which is  $\sim 0.8$  eV for Mg  $K_\alpha$  and 1.0 eV for Al  $K_\alpha$  radiation. The exact position of an XPS-signal contains a chemical shift

**Figure 4** Auger process with photoionization at level  $E_1$ , transfer of an electron from  $E_2$  to  $E_1$  and ejection of an Auger electron from level  $E_3$ .<sup>10</sup>

which has been found and interpreted first by Kai Siegbahn. An increasing charge on the atom causes a slightly higher ionization energy for any core level and thus a smaller kinetic energy or a higher binding energy  $E_B$ . As a result, one may measure energy shifts of the XP-signal, the so-called chemical shifts, which informs one about the charge of an ion or the oxidation number of an element. Electronegative binding partners similarly induce a more positive charge and thus a higher  $E_B$ . The chemical shift is often in the range of the width of the signals. The natural width of the exciting X-rays may be improved with an X-ray monochromator to  $\sim 0.5$  eV, *albeit* at the expense of intensity loss. Modern energy analyzers and sensitive detector arrays and channel plates will compensate for these losses. In many cases, one has to deconvolute a measured signal in order to separate it into the contributions of the different species. The integration of these contributing peaks yields a quantitative measure for the amount of the related species.

XPS analysis usually starts with a background subtraction, which is often achieved by a linearly increasing line or a correction according to Shirley,<sup>11</sup> that is, a curve with background contributions proportional to the preceding part of the signal. The background corrected signal is then synthesized with peaks of well characterized standards, which are usually described by Gauss–Lorentzians with appropriate parameters. The energy and shape of these peaks are usually kept constant with an adjustment of their height to get the best fit of the synthesized to the measured signal.<sup>10</sup> Usually, relative signal intensities are used (i.e., intensity ratios) in order to compensate for spectrometer characteristics such as sensitivity of the detector, the intensity of the X-ray

source, or the intensity/energy performance of the energy analyzer. The intensity ratio of two elements A and B is given by eqn [2]:

$$\frac{I_A}{I_B} = \frac{\sigma_A T_A \lambda_A D_A}{\sigma_B T_B \lambda_B D_B} \quad [2]$$

$D$  is the atomic density of components A and B. The photoionization cross-section  $\sigma$  takes care of the relative sensitivity of elements A and B to the photoionization process and is given by the data of Scofield.<sup>12</sup> The mean free path of the electrons  $\lambda$  within the specimen generally increases with kinetic energy and is given by the empirical relation of Seah and Dench<sup>13</sup> (eqn [3]).

$$\lambda = B\sqrt{E_{\text{kin}}} \quad [3]$$

Parameter  $B = 0.054 \text{ nm eV}^{-0.5}$  for elements,  $B = 0.097 \text{ nm eV}^{-0.5}$  for inorganic compounds, and  $B = 0.087 \text{ nm eV}^{-0.5}$  for organic compounds. The transmission function  $T$  depends on the specific design of the spectrometer and changes with the pass energy  $E_{\text{pass}}$  and the kinetic energy  $E_{\text{kin}}$  of the photoelectrons. Equation [4] gives the transmission function  $T$  for the VG ESCALB Mk2 analyzer as an example.

$$T = \omega^2 0.01 E_{\text{pass}}^{1.5} E_{\text{kin}}^{-0.5} \quad [4]$$

$\omega$  is the angle of acceptance of the analyzer for the electrons. In this case, the square root dependence of  $T$  and  $\lambda$  on  $E_{\text{kin}}$  cancel each other for eqn [2].

A frequent problem in corrosion is the examination of thin passive layers, that is, some few nanometers thick anodic oxide films on a metal substrate. The XPS intensity ratio of the cations and the metal atoms provides a possibility to calculate the oxide thickness. The parameters  $\sigma$ ,  $\lambda$ , and  $T$  in eqn [2] cancel, in this case due to the ratio of the same element. However the signal  $I_{\text{ox}}^{\text{Me}}$  from the cations of Me within the oxide are submitted to a self attenuation factor  $[1 - \exp(-d/\lambda_{\text{ox}}^{\text{Me}} \cos\theta)]$ , and the substrate signal  $I_{\text{Me}}^{\text{Me}}$  is attenuated by a factor  $\exp(-d/\lambda_{\text{ox}}^{\text{Me}} \cos\theta)$  due to the oxidic layer above. This attenuation is a consequence of inelastic energy losses of the photoelectrons on their way through the surface layers to the vacuum.  $d$  is the layer thickness, and  $\theta$  the angle between the direction of the detector and the surface normal of the specimen. The intensity ratio of eqn [5] indicates an increase with increasing angle  $\theta$ . This is simply due to increased masking of the electrons from the substrate, because their path through the thin oxide layer increases with  $\theta$ . Equation [6] permits the calculation of the thickness  $d$  of the passive layer.

$$\frac{I_{\text{ox}}^{\text{Me}}}{I_{\text{Me}}^{\text{Me}}} = \frac{D_{\text{ox}}^{\text{Me}}}{D_{\text{Me}}^{\text{Me}}} \cdot \frac{[1 - \exp(-d/\lambda_{\text{ox}}^{\text{Me}} \cos\theta)]}{[\exp(-d/\lambda_{\text{ox}}^{\text{Me}} \cos\theta)]} \quad [5]$$

$$d = \lambda_{\text{Me}}^{\text{ox}} \cos\theta \ln \left[ \frac{I_{\text{ox}}^{\text{Me}} D_{\text{Me}}^{\text{Me}}}{I_{\text{Me}}^{\text{Me}} D_{\text{ox}}^{\text{Me}}} + 1 \right] \quad [6]$$

In the case of an oxide layer on a metal substrate, such a calculation is quite trivial, but in a multilayered system, one must decide where the various cations and anions are located relative to each other. Angular resolved XPS measurements (ARXPS) can be used to decide the distribution of species perpendicular to the surface plane. As an example, Figure 5 presents ARXPS results from a passive layer on Fe formed at  $E = -0.16$  V in 1 M NaOH for various times in the range of 100 ms to 100 s. It is clear that a majority of Fe(III) ions are located above the Fe(II) ions, as suggested on the basis of thermodynamics.<sup>15</sup> One may further see that the passive film develops over this period of time. At 100 ms, almost no Fe(III) is present, and the bilayer structure is still not developed. With increasing time, the intensity ratio and the upward bending increase due to the growth of Fe(III) on top of Fe(II), and the Fe(II) to Fe(III) oxidation.

**Figure 5** ARXPS intensity ratio of Fe(III)/Fe(II) intensities for Fe passivated at  $E = -0.160$  V (SHE) in 1 M NaOH for different times  $t_p$  as indicated.<sup>6,14</sup>

At 100 s, the passive film has its final form and thickness. These data have been evaluated to obtain the thickness of the Fe(II) and Fe(III) layers for anodic oxidation at all potentials from the prepasive to the transpassive range as presented in Figure 6.<sup>14</sup> The film composition follows the characteristic peaks of the polarization curve of sputter cleaned iron in 1 M NaOH, which is also displayed in Figure 6. Film growth starts in this alkaline electrolyte at  $E_{P1} = -0.80$  V. Below  $E = -0.20$  V, the film contains a large fraction of Fe(II) which is oxidized at  $E_{P2} = -0.20$  V to Fe(III). At  $E > 0.20$  V, only a small residue of Fe(II) ions remain located below a growing Fe(III) film, which is at the detection limits of the method. These XPS results confirm the thermodynamic predictions of the composition of the passive layer.  $E_{P2}$  is the passivation potential of Fe in acidic

**Figure 6** Evaluation of XPS studies of Fe passivated in 1 M NaOH for 300 s on the basis of a bilayer model with Fe(II) and Fe(III) layer thicknesses of  $d_1$  and  $d_2$ , respectively. Polarization curve of sputter cleaned Fe within the spectrometer with indication of the passivation potentials  $E_{P1}$  and  $E_{P2}$ .<sup>6,14</sup>

solution, the so-called Flade potential extrapolated to pH = 13 with a  $-0.059 \text{ V/pH}$  dependence. It was interpreted as the  $\text{Fe}_3\text{O}_4$  to  $\text{Fe}_2\text{O}_3$  oxidation with thermodynamic data, which is confirmed by the XPS results.<sup>14,15</sup> In acidic electrolytes, the Fe(II) rich layer between  $E_{P1}$  and  $E_{P2}$  is not protective and dissolves immediately. However, it is protective in alkaline solution. These results may be obtained by the exclusion of air only, that is, by an investigation in the closed XPS system as described above. Fe(II) would be oxidized immediately to Fe(III) by traces of oxygen so that this species otherwise could not be found. Many passive layers have been examined in detail on pure metals and binary alloys as a function of the potential, time of passivation and electrolyte composition, in particular pH. A compilation of data and literature can be found elsewhere.<sup>6</sup> Figure 7 presents schematically the multilayered structure of passive layers on several different pure metals and binary alloys obtained by a detailed XPS analysis along with ion scattering measurements for completion. Higher valent species are found for sufficiently positive potentials only. Usually, hydroxides are outside and oxides inside. Higher valent cations are located in the outer part of the films.

**Figure 7** Schematic diagram of passive layers on various metals and binary alloys deduced from XPS and ion scattering measurements demonstrating their multilayer character.<sup>6</sup>

The lateral resolution of XPS is usually poor and corresponds to the diameter of the exciting X-ray beam (several mm). The inlet slit to the analyzer may reduce the accepted surface area of the sample to some extent. Furthermore, the beam may be focused, especially together with a monochromator, with an ellipsoidal diffracting crystal down to several micrometers only. New instruments also contain an imaging option. This can be achieved by rastering a focused X-ray beam across the sample surface. Another design uses lenses at the entrance and exit of the analyzer to focus an image of the whole specimen or a major part of it onto a channel plate, which registers an image of the elemental distribution at the surface. Modern spectrometers allow a switching from a spectroscopic mode registering XPS to an imaging mode registering the elemental distribution of any element, which is chosen by its binding energy at the spectrometer control unit.

In addition to the basic research, XPS may also be used for a wide variety of industry problems. Besides the investigation of corrosion problems and corrosion layers, it may be used to study polymers, semiconductors, and insulators. One may investigate contaminations and surface problems in the production of any kind. Many laboratories of surface analysis help the industry and other institutes to provide a fast solution for their problems. A serious component of such activity is, ensuring that the specimen is obtained and prepared without the contamination of its surface in order to get results which are relevant to the technical situation.

## 2.31.4 Ultraviolet Photoelectron Spectroscopy

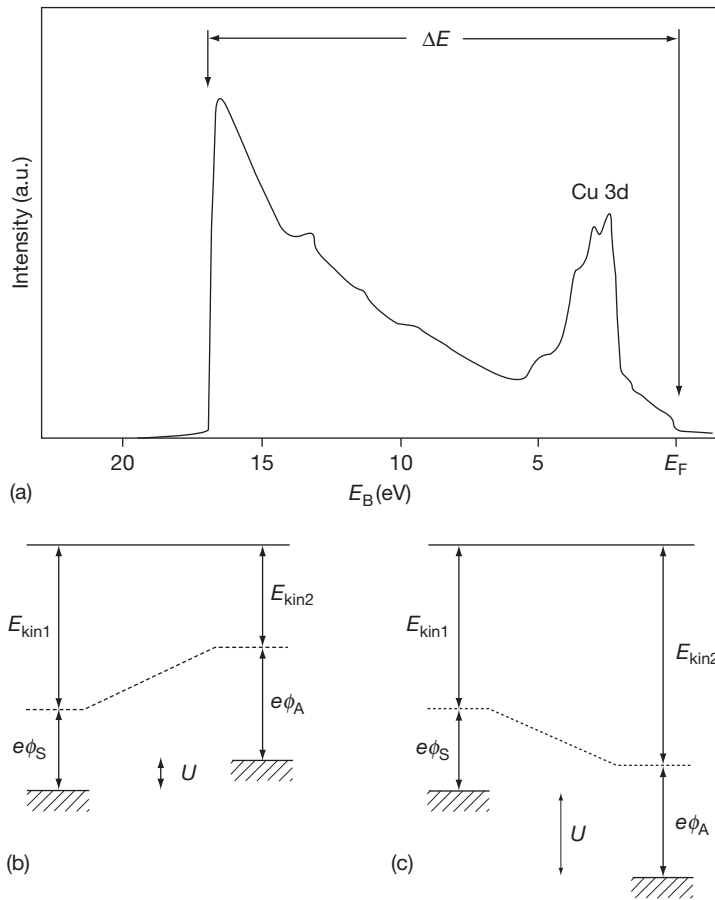

In ultraviolet photoelectron spectroscopy (UPS), a surface is irradiated with UV light, usually the He I (21.2 eV) or the He II line (40.8 eV), from a lamp attached to the analysis chamber of a spectrometer. The UV-light of the helium discharge is transmitted via a capillary to the specimen's surface, which permits a sufficiently high transmission without ruining the vacuum. As the excitation energy is low compared to the XPS, one only gets contributions to the photoelectron spectrum from low binding energy levels, including the valence band. Thus, UPS mirrors the broad distribution of states of the conduction band of a metal and the valence band of a semiconductor or insulator. Consequently, interpretation of the data can rather be more involved than

for XPS. One straightforward, but important, application of UPS is the determination of the work function  $e\Phi_W$  of a metal, or the threshold energy  $e\Phi_{Th}$  of a semiconductor or insulator ( $e\Phi_{Th}$  = difference between the upper valence band edge and the vacuum level). **Figures 8(a) and 9** show UP-spectra of Cu-metal without and with a thin passive layer of  $\text{Cu}_2\text{O}$ , respectively. One may see clearly the contribution of the surface oxide to the spectrum. **Figures 8(b) and 8(c)** show the potential wells of Cu metal and the analyzer with the related work functions similar to **Figure 3(a)**. Application of a negative bias to the specimen of  $\sim U = -5\text{ V}$  ensures that all photoelectrons reach the analyzer (**Figure 8(c)**). This bias negates a potential barrier which the electrons would otherwise have to overcome, as presented in **Figure 8(b)**, causing a drop off of the UV-spectrum at the low energy side close to  $E_{kin} = 0\text{ eV}$ . There exists

the obvious relationship, indicated in **eqn [7]**, between the work function  $e\Phi_W$ , the kinetic energy  $E_{kin}$ , and the width  $\Delta E$  of the spectrum. The cutoff edge in the biased spectra corresponds to photoelectrons with  $E_{kin} = 0\text{ eV}$ , which have been excited from deeper levels within the valence band, or which have lost their kinetic energy due to inelastic interactions. Similarly, **eqn [8]** allows one to deduce the threshold energy  $e\Phi_{Th}$  of a semiconductor or insulator. These equations and data have been used to determine  $e\Phi_W$  of Cu and  $e\Phi_{Th}$  of its anodic oxides and thus the absolute value of the Fermi energy of a bare Cu electrode immersed from the electrolyte at appropriate potentials and of the upper valence band edge of its anodic oxides.<sup>6</sup>

$$e\Phi_W = h\nu - \Delta E \quad [7]$$

$$e\Phi_{Th} = h\nu - \Delta E \quad [8]$$

### 2.31.5 Auger Electron Spectroscopy

If an electron is emitted from its orbital, the remaining hole may be filled by a more energetic electron. The energy difference between the two electrons leads to characteristic X-ray fluorescence or to the ejection of a third electron, the Auger electron, as competing processes (Figure 3). Such emission may be initiated by X-rays or incoming electrons, corresponding to the X-ray and electron induced AES. In the XPS subsection, it has been mentioned briefly that Auger lines are present in XP-spectra. These Auger lines are sometimes relied upon for the determination of the chemical state, when the chemical shift of XP lines is so small that it cannot be resolved with XPS, as is the case for Cu metal and Cu(I) oxide. In Figure 10, the Cu LMM line acquired from a thin  $\text{Cu}_2\text{O}$  film on Cu has been deconvoluted with the aid of the Auger lines from appropriate Cu reference compounds. From these quantitative data for the two Cu species, the thickness of the  $\text{Cu}_2\text{O}$  layer has been determined in good agreement with electrochemical results.<sup>16</sup> However, the AES lines are usually more complicated due to the three electron process of AES which requires more effort for a reliable quantitative evaluation. Therefore, AES is used for a chemical analysis mainly if the chemical shift for XPS is too small to distinguish between the two species.

Electron induced AES is of greater importance for surface analysis. The beam from an electron source may be focused by a lens to a sufficiently small spot, so that one may get AE-spectra with very high lateral resolution of  $\sim 10$  nm. Modern high intensity electron

**Figure 10** X-ray induced LMM Auger signal of a Cu specimen passivated in 1 M NaOH with a  $\sim 2$  nm  $\text{Cu}_2\text{O}$  overlayer, and its separation into contributions from Cu and  $\text{Cu}_2\text{O}$ , respectively,<sup>10,16</sup> using reference compound data.

sources use thermoionic emission or field assisted emission of electrons as, for example, from  $\text{LaB}_6$  filaments or pin shaped Schottky emitters. Given these source characteristics, AES has been used for local spot analysis, line profiles, or even an elemental mapping, that is, imaging with respect to the elements of interest by scanning the beam. In corrosion, many localized effects are of decisive importance like inclusions and local attack at these sites, pitting and crevice corrosion, and grain boundary segregation and grain boundary attack. In all these cases, information on the distribution of metal components, impurities, and corrosion products is important to understand the leading mechanisms which require surface analysis with high lateral resolution.

Conventional electron induced AES yields the first derivative of the Auger lines. This is a consequence of modulation of the pass energy of the energy analyzer, usually by 5–10 mV together with the application of lock-in techniques. The obtained signal is therefore the first derivative of the Auger line with respect to the energy scale. The advantage is removal of a large and especially seriously changing background, which is the case for Auger signals of elements like Si at low kinetic energy. The disadvantage of differentiated signals is the loss of some

information. In modern spectrometers, the sensitivity is high enough to measure the nondifferentiated signal, which provides the advantages mentioned above.

Auger lines are named using the electronic levels involved in the process, for example, KLL. The first letter describes the orbital which is ionized by the impinging electrons or X-rays, the second is associated with the level from which an electron falls into the hole, and the third is the level from where the Auger electron is emitted. A KLL process starts with the ionization of a K shell, followed by a transfer of a L-electron to the core hole, and finally transfer of the energy difference to a third electron from the L-shell. The energy of the Auger electron is thus determined by the three involved energy levels. Due to spin-orbit coupling, the p- and d-electrons of the L and M shells are split into different levels, for example, L<sub>1</sub>–L<sub>3</sub> (s, 2p<sub>1/2</sub> and 2p<sub>3/2</sub>), leading to the nomenclature KL<sub>1</sub>L<sub>2,3</sub> for an Auger line. Thus, Auger lines are more complicated compared to XPS and therefore a quantitative evaluation including different oxidation states requires more effort. If electrons of the valence band are involved, their description contains V, for example, LVV for an electron ejected from the L shell with two additional electrons involved from the valence band.

## 2.31.6 Ion Spectrometry

The backscattering of noble gas ions has been developed into techniques for elemental analysis of surfaces and surface films. Two main approaches are described here: the backscattering of He- or Ne-ions with a primary energy of 1–5 keV (ISS, or low energy ion scattering (LEIS)) and the backscattering of He with a primary energy of 2 MeV (RBS). In addition, SIMS will also be discussed in this subsection.

### 2.31.6.1 Ion Scattering Spectrometry or Low Energy Ion Scattering

In ISS, only impinging ions, which are backscattered by the outermost atomic layer of a surface, have a small, but significant, probability of emerging charged. At the second or any deeper layer, essentially all noble gas ions pick up an electron and are scattered as neutral atoms. Given that only charged particles are detected, using an electrostatic energy analyzer as employed for XPS but with reversed polarity, ISS detects the composition of the outermost surface layer. A soft sputter process yields a depth profile of the surface region

with a monolayer resolution. The energy loss suffered by scattered ions of mass  $m$  is described by eqn [9a], where  $E$  is the ion energy after scattering, and  $E_0$  the primary energy. If the backscattering angle between the primary beam and the scattered ions is  $\Theta = 90^\circ$ , eqn [9a] simplifies to eqn [9b]. In this geometry, each target mass  $M$  will lead to an energy loss with a characteristic  $E/E_0$  ratio depending on the involved masses  $m$  and  $M$  only.

$$\frac{E}{E_0} = \frac{m^2}{(m+M)^2} \left\{ \left[ \cos\theta + \left( \frac{M^2}{m^2} - \sin^2\theta \right) \right]^{1/2} \right\}^2 \quad [9a]$$

$$\frac{E}{E_0} = \frac{M-m}{M+m} \quad [9b]$$

Thus, the energy spectrum of the backscattered ions leads to a peak for each target mass  $M$ . The integrated peak areas provide a measure of the amount of atoms within the surface. After calibration for the backscattering cross section, that is, the relative sensitivity of the elements, one may calculate quantitative results for surface concentrations. In combination with sputtering, one gets a quantitative depth profile. Figure 11 shows the depth profiles of Cr for a Fe15Cr

**Figure 11** Quantitative ISS depth profiles of Fe15Cr passivated at  $E = 0.90$  V in  $0.5$  M  $\text{H}_2\text{SO}_4$  for different times in the range of 1 min to 1 week.<sup>6</sup>

electrode passivated in 0.5 M  $\text{H}_2\text{SO}_4$  at  $E = 0.90$  V for different times in the range of 1 min to 1 week.<sup>6</sup> The profile demonstrates that the passive layer is significantly enriched in Cr. At the right side, it levels off to 15% Cr for the bulk metal alloy. The outermost surface is only slightly enriched in Cr. Apparently, the Cr content accumulates on the surface region during passivation. Also, the maximum gets slightly higher with time from 58% for 1 min to 70% Cr for 1 week. These results agree well with those obtained by XPS. In contrast to XPS, which provides chemical information, the advantage of ISS is the high depth resolution for this 2 nm film. Therefore, both methods are complementary to each other. The high enrichment of Cr(III) ions within the layer is a consequence of their extremely slow dissolution rate, 1–2 orders of magnitude smaller than Fe(III). This property in turn is the reason for the excellent stability of FeCr alloys and FeCrNi stainless steel in comparison to iron.

### 2.31.6.2 Rutherford Back Scattering

For RBS He ions are accelerated by a high voltage to 2 MeV, provided by a Van der Graaf generator. These high energy ions may penetrate materials to a

maximum depth of  $\sim 1 \mu\text{m}$ . They are backscattered at the nuclei of atoms at different depths and then get back to the surface where they are measured at a backscattering angle of  $\Theta = 175^\circ$  by a solid state detector. The ring shaped Si-detector contains a hole for the primary impinging beam. Two kinds of energy losses are obtained, the loss by the backscattering process which follows eqn [9], and the losses due to 'inelastic' processes of the ions on their way in and out. The latter depend on the kinetic energy and may be taken from tables for the stopping cross sections. As a result, one obtains broad signals whose leading edge is characteristic of the mass of the target atoms and whose width corresponds to the depth. The height is proportional to the concentration of the atoms when corrected for the element's sensitivity. The intensity increases with the square of the atomic number. Figure 12 shows an example of RBS from an Al 1%Cu vapor deposited film, before and after anodization to 100 V in citrate buffer pH 6.0.<sup>6,17</sup> The leading edge of Cu is at high energy due to its larger mass well separated from the light metal Al. A step in the Al signal after anodization corresponds to the grown  $\text{Al}_2\text{O}_3$  anodic film with a smaller Al-concentration compared to the metal substrate. Its width is a measure of the oxide thickness.

**Figure 12** RBS spectrum of vapor deposited Al 1 at. % Cu film on quartz substrate before and after passivation with  $i = 1 \text{ mA cm}^{-2}$  at 100 V in citrate buffer pH = 6.0.<sup>17</sup>

The oxygen signal of the anodic oxide is superimposed on the signal of Si from the quartz substrate for the vapor deposited metal film. The leading edge of the Cu signal shows a shift to smaller energies, due to the formation of the anodic oxide which is Cu free. A superimposed small peak close to its leading edge corresponds to Cu accumulation at the metal surface underneath the oxide. In the case of anodization of these Al/Cu films Cu accumulation at the metal surface finally causes a film breakthrough and a destruction of the vapor deposited metal film. This example demonstrates that one obtains nondestructive depth profiles of corroding surfaces by RBS which explain the details of elemental distribution and their changes during the reactions.

### 2.31.6.3 SIMS and Related Methods

If an ion beam strikes a surface, the energy of the impact is transmitted to atoms and molecules of the specimen, which causes their transfer to the vacuum. These ions may be submitted to mass analysis for their identification. For the mass separation, quadrupole mass analyzers may be used instead of magnetic sector analyzers. Another possibility is time-of-flight mass spectrometers (TOF-SIMS). In this case, a pulsed ion beam creates bunches of secondary species, which are accelerated to a fixed kinetic energy. Given  $E_{\text{kin}} = 1/2mv^2$ , lighter ions travel faster, and so arrive at the detector quicker than the heavier ones. These ions are detected by a channeltron or a channel plate. Mass spectrometry is very sensitive, so traces of species may be detected. Furthermore, the method may distinguish between the various isotopes of one element and may also separate species with only slight mass changes, less than one unit due to the mass defect. It is also one of the few methods which may detect hydrogen which is not seen by methods such as XPS or AES. A frequent application is the determination of dopants in semiconductors and their depth profiles which may be measured by ion sputtering and SIMS. The method is also important for electrode kinetics and corrosion research. As isotopes may be separated by the method, one may study the incorporation of oxygen during anodic film growth on an already preexisting layer by SIMS depth profiling. The distribution of the  $\text{O}^{18}$ -isotope within anodic oxide grown in  $\text{O}^{18}$ -enriched water may help distinguish, where new oxide is formed at the metal surface or at the oxide-electrolyte interface. This enables the measurement of transfer rates of oxygen anions versus metal cations

within the preexisting anodic oxide film. It has been found that oxygen ions can migrate inward<sup>18</sup> while metal cations are moving outward. These results have been confirmed by the study of the movement of Xe-implants in oxide films by RBS during further oxide growth. High intensity ion sources like liquid metal ion sources with Cs and Ga permit a very small focus of the beam from 5  $\mu\text{m}$  to <20 nm. These ion guns facilitate the study of corrosion processes with high lateral resolution and allow imaging by SIMS showing the lateral distribution of elements with appropriate resolution.

SIMS may be used as a quantitative method. However, the SIMS signal depends strongly on the matrix, that is, the electronic conditions at the specimen's surface. A metal with a high concentration of electrons at the Fermi level causes a high probability of neutralization via tunnel processes for the ions immediately in front of the surface. Therefore, the SIMS signal of cations is very small for pure metal surfaces, whereas it gets much higher if the specimen is covered with a thin semiconducting or insulating oxide film, due to its band gap where no electrons are available. The SIMS signal may vary for the same concentration of species by orders of magnitude. However, it will be fixed if the interesting species is a dopant in a matrix which does not change during ion impact. This is the case for the analysis of dopant implants in semiconductors. One possibility to stabilize the SIMS efficiency is the inlet of small amounts of oxygen to the surface of the metal forming a thin layer of semiconducting oxide. Another is the ionization of the neutrals after their sputtering with an electron beam, or by the stabilized formation of secondary ion species by a glow discharge (GD).

An ion beam may also be used to remove large ionized molecules from a metal surface. These processes have been studied in detail by SIMS of large organic molecules deposited on Ag. In this case, one obtains the  $\text{M}^+$ , the  $[\text{M} + \text{H}]^+$  and the  $\text{AgM}^+$  signals, besides fractions of the molecule M. Apparently, the energy of the ion beam is distributed via a cascade to the site of the molecule, which then finally is responsible for its transfer to the vacuum. The chemical interaction of the molecules with the silver surface causes the  $\text{AgM}^+$  peak. A very similar mass spectrometry of organic molecules is matrix assisted laser desorption (MALDI). For this analytical method, the organic molecules are codeposited with a matrix molecule at a metal surface, mostly a derivative of benzoic acid. The matrix is vaporized by a pulsed laser beam which ionizes and transfers the embedded molecules together with the matrix to the vacuum.

After acceleration by a voltage in the range of 10–30 keV, the molecules are analyzed and detected by a TOF-mass spectrometer. Very large masses have been detected by MALDI-TOF up to  $10^6$  mass units. TOF mass spectrometry is an excellent tool to study organic films, inhibitors and polymers due to the high mass range of up to  $10^6$  atomic mass units which is accessible to this method.

### 2.31.7 Methods Using Hard X-rays: X-ray Diffraction (XRD), X-ray Reflectivity (XRR), and X-ray Absorption Spectroscopy (XAS)

In the laboratory, sealed X-ray tubes are the most widely used X-ray sources, which emit continuous Bremsstrahlung-radiation as well as characteristic X-ray emission lines. The X-rays are excited by an accelerated electron beam impinging on a metal target within a vacuum tube. Although the maximum electrical input power of such an X-ray tube is typically about several kilowatts, the resulting X-ray intensities which are measured on a sample surface are relatively weak, because typically, only fractions of a percent of this electric input power is transformed into X-ray radiation leaving the tube through X-ray windows (typically beryllium). This is a serious drawback for *in situ* investigations of electrodes and related corrosion processes, since the parasitic absorption by the electrolyte further reduces the intensity which is available for the experiments. Assuming, for example, a rotating anode X-ray tube which provides  $\sim 10^6$  monochromatic X-ray photons per second per square millimeter, a Bragg reflectivity of a real sample (such as a passive film on a metal substrate) of  $\sim 10^{-3}\%$  and a transmission of the electrochemical cell of  $\sim 10\%$ , we end up with a single photon per second only. In a practical diffraction experiment, thus, an extremely large accumulation time is required for each data point in order to achieve a useful signal to noise ratio even in the photon counting mode using sophisticated detector equipment. Nevertheless, some few *in situ* experiments with laboratory equipment have been reported in literature.

Much more intense X-ray beams are provided by synchrotron radiation (SR).<sup>19</sup> SR is generated when charged high energy particles (usually electrons or positrons with kinetic energies of  $\sim 2$ – $8$  GeV) are moving on a curved path which is induced by a magnetic structure. Compared to X-ray anodes, SR has a continuous emission spectrum ranging from the

IR to hard X-rays. It is well defined and can be calculated from the knowledge of the local curvature of the electron path and the energy of the stored electrons or positrons.<sup>19</sup> The quality of the emitted radiation is characterized by its brightness and brilliance. The latter parameter is defined by the number of photons which is emitted in one second from a source area of  $1 \text{ mm}^2$  into a cone defined by  $1 \text{ mrad}^2$  normalized to a spectral band width of  $0.1\%$ .<sup>19</sup> In Figure 13, the brilliance of some synchrotron sources is illustrated as a function of the photon energy. For comparison, the radiation emitted by a rotating anode with a point focus is  $\sim 10^{10}$  photons/( $\text{s mm}^2 \text{ mrad}^2 0.1\%$ ), which is at the lower end of the scale of Figure 13. In contrast to the discrete line spectrum which is provided by the emission lines of an X-ray anode, the SR storage ring emits over a large range of energy from the IR to hard X-rays. Thus, the energy (wavelength) for the experiments can be selected freely from this continuum and allows an optimization depending on the actual sample or problem

**Figure 13** Average brilliance for different radiation sources at HASYLAB (DESY, Germany), BESSY (Berlin, Germany) and the ESRF (Grenoble, France). For comparison, the brilliance expected for future sources (free electron lasers) is also depicted. Courtesy of P. Gürtler, HASYLAB.

under investigation. For the application of extended X-ray absorption spectroscopy (EXAFS, see below), the use of SR is mandatory, since the photon energy is scanned over  $\sim 1$  keV in these experiments. Here, even for a simple transmission mode experiment, the Bremsstrahlung-continuum of X-ray tubes is much too weak in intensity.

While second generation SR sources make use of the radiation emitted by bending magnets, sophisticated periodic magnet-structures (insertion devices, wigglers, and undulators) are installed at third generation synchrotron sources. The periodic field inside these devices forces the passing electrons and positrons on a sinusoidal path. Depending on the magnetic field strength, the magnetic gap and the number of antiparallel arranged magnets, the individual emission processes are without any phase relation (wiggler: strong field, small number of periods) or in phase (undulator: weak field, large number of undulator periods), improving the spectral brightness by at least two orders of magnitude compared to a bending magnet (see [Figure 13](#)). This means that SR is able to provide highly intense monochromatic radiation with extremely small lateral and horizontal divergence. These properties are an indispensable prerequisite for example, for surface X-ray scattering or diffraction experiments, especially in an electrochemical environment.

The charge carriers in a storage ring are generally accumulated in small bunches, the size of which is measured in terms of the time which is necessary to pass the focal point of the experiment. While the length of an individual bunch is of the order of several picoseconds, the distance between two bunches amounts to several nanoseconds. Therefore, SR enables time resolved experiments using this periodic bunch structure. Furthermore, due to the fact that the accelerated particles are kept in the orbit plane, the emitted synchrotron light is generally linearly polarized in this plane. This is important with regard to investigations of highly anisotropic systems such as adsorbates on single crystal surfaces. In addition, slightly below and above the orbit plane, SR-light is circularly polarized, which gives unique experimental opportunities for the investigation of magnetic materials and newly constructed insertion devices provide circularly polarized light with extremely high brilliance even in the orbit plane.

The increased availability of intense SR light sources, especially those of the new third generation, has its benefit for *in situ* investigations of corrosion processes, such as localized corrosion or passivation. *In situ* studies of electrode surfaces with X-rays

generally suffer from the parasitic absorption by the electrolyte. While this effect can be tolerated at high X-ray energies of  $\sim 15$  keV or more, the absorption of the electrolyte increases dramatically with decreasing photon energy. For example, for energies  $\sim 25$  keV, a 10 mm electrolyte (water) layer has an X-ray transmission of  $\sim 65\%$ , while at the energy of the Cu  $K_{\alpha}$ -emission line ( $\sim 8.0$  keV), the transmission of an electrolyte layer of only 3 mm decreases to  $\sim 12\%$ . While for X-ray scattering or diffraction experiments, this parasitic absorption by the electrolyte can be circumvented simply by using higher photon energies, it is a crucial drawback for XAS, since the electrode material with its characteristic absorption edges predefines the energy range which is necessary for the experiments. Depending on the scientific problem and the chosen experimental technique, different types of *in situ* cells have been applied, meeting both the experimental requirements for electrochemistry and the chosen analytical methods and techniques. A schematic representation of several different cell geometries is given in [Figure 14](#). Simple transmission type cells ([Figure 14\(a\)](#)) may be used for XRD and XRR experiments, and they are also suited to the study of corrosion products within the electrolyte.<sup>20</sup> A number of studies of pitting corrosion applied this geometry for the investigation of artificial pits also.

**Figure 14** Schematic representations of different electrochemical cells for *in situ* studies of corrosion processes. (a) Transmission type cells which may be used for investigations of the electrode using X-ray diffraction (XRD), reflection mode X-ray spectroscopy as well as for the characterization of the electrolyte in front of the electrode, for example, for the spectroscopic identification of corrosion products. (b) Cell geometry which is optimized for diffraction experiments. (c) Thin layer cell favorable for fluorescence spectroscopy or diffraction experiments of electrode surfaces. While the electrochemical preparation is performed with an inflated window allowing an unhindered mass transport from and to the electrode surface, the thin elastic window is pressed onto the surface of the electrode for the X-ray measurements with a thin electrolyte layer remaining in order to retain potential control. WE – working electrode, W – X-ray window, E – electrolyte.

A second type of cell is optimized for XRD experiments (**Figure 14(b)**).<sup>21</sup> It mainly consists of a cylindrical body with a sample holder and a hemispherical X-ray window of fused silica. Due to its symmetry, all solid angles in the hemisphere above the sample surface are accessible for the incident and reflected beam. Since the X-ray path length in the electrolyte and the window material are angle independent, this cell design is ideal for diffraction, surface diffraction as well as for XRR studies.<sup>21</sup>

A third type of electrochemical cells reduces the electrolyte to a thin film with a typical thickness well below 10–20  $\mu\text{m}$ , which is trapped between the sample (working electrode, WE) and an organic polymer film (polypropylene, Mylar, Kapton, etc.) of a few  $\mu\text{m}$  thickness.<sup>22</sup> Such a cell, presented schematically in **Figure 14(c)**, is well suited for fluorescence mode detection experiments and X-ray standing wave techniques<sup>22,23</sup> since the path length of the detected fluorescence photons is minimized and independent from the incidence angle  $\Theta$ . However, for surface sensitive studies, the grazing incidence geometry with glancing angles of typically below  $0.5^\circ$  is mandatory, so that the path length of the X-rays in the electrolyte and the window material increase dramatically causing an enhanced parasitic absorption of the impinging and also the emerging radiation accordingly. As a result, *in situ* studies of electrode surfaces are currently limited to X-ray energies of above  $\sim 6000$  eV, even if state of the art detector equipment such as multielement solid state detectors<sup>22,24</sup> and high flux insertion device beamlines at third generation storage rings are used. For investigations of dynamical processes consuming species from the solution or generating significant amounts of soluble reaction products, cells with a thin layer geometry cannot be used due to the strongly restrained mass transfer from and to the WE. In this case, cells without mass transfer limitations such as the transmission type cells (**Figure 14(a) and 14(b)**) have to be applied or the electrode has to reach a stationary state with low reaction rates prior to the measurement in order to avoid erroneous results or misinterpretation.

### 2.31.7.1 X-ray Diffraction

The XRD technique is based on the elastic scattering of X-rays from structures that have long range order as schematically shown in **Figure 15**. X-rays reflected at net planes parallel to the surface may lead to constructive interference (Bragg-peak) if the incidence angle  $\Theta$  (Bragg-angle) between the

**Figure 15** Basic principle of XRD. For constructive interference, that is, the observation of a Bragg-peak, the path length difference between the interfering X-rays has to be an integer multiple of the X-ray wavelength  $\lambda$  as shown for the lattice planes with the black atoms. If a second net plane (white atoms) is inserted, the diffracted intensities are influenced accordingly. See text for more details.

impinging radiation and the lattice planes satisfies the relation

$$n\lambda = 2d\sin\Theta, \quad [10]$$

where  $\lambda$  is the X-ray wavelength, and  $d$  the lattice spacing of the sample under investigation. In general, not only the fundamental wave ( $n = 1$ ) but also higher harmonics ( $n > 1$ ) are observed in a diffraction experiment. The interpretation of eqn [10] is illustrated in **Figure 15**, that is, constructive interference only occurs, if the optical path difference between the X-rays which are diffracted from neighboring lattice planes is equal to an integer multiple of the X-ray wavelength  $\lambda$ . The resulting diffraction pattern is representative of the crystal structure because each crystal structure is characterized by the distribution of its lattice atoms in the unit cell. If, for example, a second lattice plane is present in between those considered as first (open dots in **Figure 15**), this inserted plane may alter the diffraction pattern significantly as follows. If the distance between the two planes is equal to a quarter of the original  $d$ -spacing, then the path difference for the inserted net-plane equals half of the wavelength for  $n = 2$ , that is, destructive interference occurs. This is the case, for example, for the (222)-reflections of Si and Ge. In general, this behavior is mathematically described by the so-called structure factors  $F_{hkl}$ , which include the positions of all the atoms in the crystal structure under investigation as well as their occupation by different types of atoms according to eqn [11].

$$F_{hkl} = \sum_n f_n \exp(2\pi i Q R_n) \quad [11]$$

$$R_n = n_1 a_1 + n_2 a_2 + n_3 a_3 \quad [12]$$

$$Q = b_1 b_1^* + b_2 b_2^* + b_3 b_3^* \quad [13]$$

Here  $R_n$  is the lattice vector of the  $n$ th atom (eqn. [12]), with  $a_1$ ,  $a_2$ , and  $a_3$  as the basis of the unit cell unit and  $n_1$ – $n_3$  are integer numbers.  $Q$  is the reciprocal lattice vector which corresponds to the scattering processes at the  $(hkl)$ -lattice planes (eqn [13]).<sup>25</sup> Again,  $b_1$ – $b_3$  are integer numbers, and the reciprocal lattice is connected to the real space representation by  $a_i b_j^* = 2\pi \delta_{ij}$  (for  $i = 1, 2, 3$ ,  $\delta_{ij} = 1$  for  $i = j$ ,  $\delta_{ij} = 0$  for  $i \neq j$ ).

If  $Q$  is given by the difference between the  $K$ -vector of the scattered X-rays and the impinging radiation, that is,  $Q = K_f - K_i$  as can be seen in Figure 16, where a schematic representation of different diffraction geometries is given, then we may expect a Bragg-peak for the corresponding angles. The summation in eqn [11] includes all the atoms in

**Figure 16** Schematic presentation of the scattering geometry in an XRD experiment (Laue-case). A Bragg peak is observed if the difference between the wave vector of the Bragg-reflected beam  $K_f$  and the impinging radiation  $K_i$  is identical to a reciprocal lattice vector  $Q$ . The Bragg angle  $\theta_B$  is identical to the angle between the diffracted wave and the  $(hkl)$ -lattice plane, which is not necessarily parallel to the surface of the crystal under investigation. Three different types of scans are indicated. (a) Out-of-plane scan ( $Q_z$  or  $Q_{\perp}$ -scan): the rotation ( $\Phi$ ) of the crystal is fixed, and data are measured by varying the component of  $Q$  normal to the surface (which is named  $Q_z$  or  $Q_{\perp}$ ) while the component parallel to the surface ( $Q_{\parallel}$ ) is fixed. (b) In-plane radial scan ( $Q_{\parallel}$ -scan): the component of  $Q$  along the surface is varied. The direction of  $Q$  is kept, but its magnitude is varied by changing the incident and diffracted angles ( $\theta$  and  $2\theta$ ) symmetrically. (c) Phi-scan: the crystal rotates about its surface normal with the positions of the incident and diffracted beams fixed. The magnitude of  $Q$  is fixed for this scan while the direction of  $Q$  rotates.

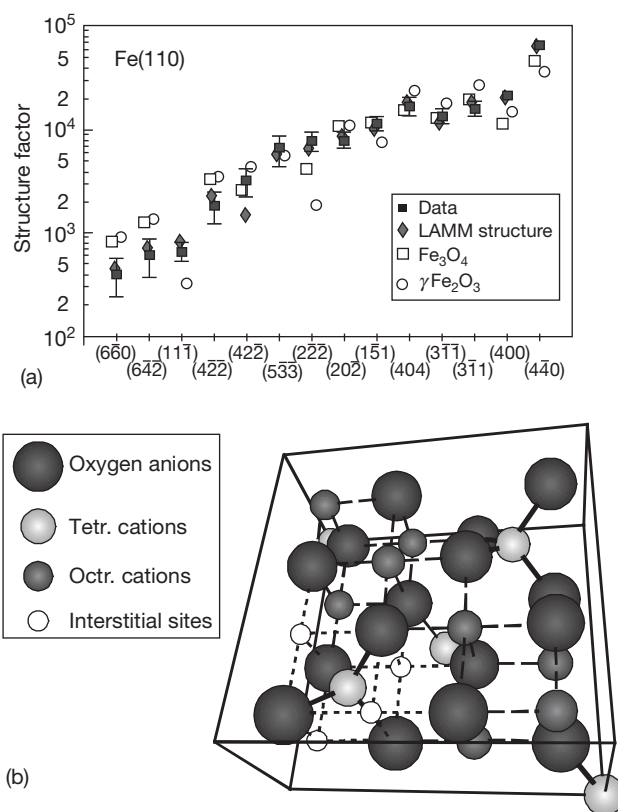

the unit cell, and  $f_n$  is the atom form factor, which represents the scattering power of an individual atom. Basically,  $f_n$  is determined by the number and the distribution of the electrons belonging to a single atom.<sup>25</sup> Values for  $f_n$  are tabulated elsewhere.<sup>26</sup> The diffracted intensity then is given by eqn [14]

$$I \propto |F_{hkl}|^2 \quad [14]$$

and thus not only the positions of the diffraction peaks are representative of the crystal structure, but also their intensities, and characteristic diffraction patterns result for each individual crystal structure.

As an example from corrosion research, we present results determined from a diffraction experiment of passive layers on iron in borate buffer solution.<sup>27,28</sup> It should be mentioned here that a long and controversial discussion has been carried out and that contradicting results have been obtained.<sup>6,24</sup> Both amorphous as well as different crystalline structures have been proposed. Thus, an *in situ* diffraction experiment is very helpful for a structure determination. Due to the weak scattering intensities, focused SR as well as sophisticated detector equipment was used to obtain reliable data quality.<sup>27,28</sup> In Figure 17(a), the structure factors obtained for different diffraction peaks for the passive film on Fe(110) are compared to those of several different model compounds. Based on the measured symmetry, lattice constants and the detected Bragg-peak intensities, the passive layer data are most consistent with oxides of the spinel type (e.g.,  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-Fe}_2\text{O}_3$ ), while all other crystalline iron oxides, hydroxides or oxy-hydroxides are not compatible to the measured diffractograms. As can easily be seen, however, there are statistically significant deviations between the  $F_{hkl}$  of the measured data and those of the model compounds  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-Fe}_2\text{O}_3$ . Furthermore, linear combinations of the  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-Fe}_2\text{O}_3$  model compounds are not able to fit the experimental data sufficiently, and thus, a refinement of the structure was performed, yielding the structure presented in Figure 17(b), that is, the LAMM phase. Without going too much into the details, it should be mentioned here that the spinel unit cell which contains 32 oxygen anions, 16 octahedral, and eight tetrahedral cation sites is fully occupied in  $\text{Fe}_3\text{O}_4$ . For  $\gamma\text{-Fe}_2\text{O}_3$ , a quarter of the octahedral sites have only 33% occupancy, the remaining octahedral and tetrahedral sites being fully occupied. Both spinel reference compounds do not contain any interstitial ions. The authors found an octahedral site occupancy of  $(80 \pm 10)\%$  and a tetrahedral site occupancy of  $(66 \pm 10)\%$  for the passive film. While no evidence

**Figure 17** (a) Comparison of the experimental structure factors (filled squares) with those of selected Fe-oxide model compounds for the passive layer on Fe(110): open squares for  $\text{Fe}_3\text{O}_4$ , open circles for  $\gamma\text{-Fe}_2\text{O}_3$ , and filled diamonds for the 'LAMM'-phase. Reproduced from Toney, M. F.; Davenport, A. J.; Oblonsky, L. J.; Ryan, M. P.; Vitus, C. M. *Phys. Rev. Lett.* **1997**, 79, 4282–4285. (b) Schematic illustration of the passive film structure (LAMM-structure). The solid black lines are the borders of the bottom half of the unit cell (big spheres: oxygen anions, fully occupied; smaller light grey spheres: tetrahedral cation sites, 66% occupancy; dark grey spheres: octahedral cation sites, 80% occupancy). Four of the eight octahedral interstitial sites are indicated by small white spheres, four additional sites are located in the upper right hand section which is not shown. Note that the interstitials are shown in well defined positions for clarity, while in the LAMM-structure used for the fitting of the diffractograms, they are distributed randomly in the structure. Bonds are also indicated for clarity: bold, dashed, and dotted lines for the tetrahedral, octahedral, and octahedral interstitial bonds, respectively. Adapted from Toney, M. F.; Davenport, A. J.; Oblonsky, L. J.; Ryan, M. P.; Vitus, C. M. *Phys. Rev. Lett.* **1997**, 79, 4282–4285.

for tetrahedral interstitials was found, there are cations occupying  $(12 \pm 4)\%$  of the available octahedral interstitial sites.<sup>27,28</sup> The large Debye–Waller factors (0.01 nm up to 0.028 nm) which are needed to fit the experimental data are the indication of the static disorder in the film, which results from the bond length variations induced by the interstitials and vacancies, and may explain why previous X-ray absorption spectroscopic investigations also found evidence for amorphous structures.

For real corroding systems, the interpretation of diffraction patterns in comparison to the data for passive layers on single crystal Fe-electrodes is even more complicated. A sample in practice consists of crystallites of different but eventually some preferential orientation, that is, a certain texture at the

surface. As a consequence, the Bragg reflexes of all other orientations are suppressed in their intensity compared to those expected from the calculated structure factors. Such a behavior is well known for example, for vapor deposited thin films. Furthermore, a diffraction pattern is also modified by the presence of defects in the crystal lattice. For example, stacking faults in the sample cause systematic shifts and a characteristic broadening of the diffraction peaks.<sup>29</sup> Some of the peaks remain stable in position and half width, while others systematically move toward larger or smaller Bragg angles in conjunction with broadening. Even peak splitting is observed for special defect structures. Stress and strain also cause systematic Bragg peak shifts.<sup>30</sup> Therefore, the detailed analysis of peak positions shifts, their widths, and

intensities can be used for the identification of existing defects, as shown elsewhere.<sup>27,31</sup> For example, in the case of the passive film on Ni single crystal electrodes in sulfuric acid, a tilt of the oxide structure with respect to the underlying Ni-metal was found.<sup>31</sup>

When finite size effects are included, the width of measured Bragg peaks are found to be inversely related to the dimension of the diffracting region of the crystal. Thus, line broadening provides information about the particle size  $D$  of small crystallites which may be calculated by the application of the Scherrer formula of eqn [15]:

$$D = \frac{K\lambda}{\Delta\theta \cos\theta} \quad [15]$$

where  $K$  is the Scherrer constant, which depends on the shape of the crystallites under investigation and in most cases is close to 0.9, and  $\Delta\theta$  is the line width at half maximum in radians after correction for instrumental broadening.<sup>30</sup> Although it is not trivial to separate the different contributions, information about the particle size distribution can be obtained from a more complete line shape Fourier-analysis.<sup>30</sup> In this regard, the use of SR may simplify the data interpretation. Compared to a laboratory experiment, the experimental line width is drastically reduced due to the extremely small divergence of SR-beams. In the case of the Fe passive layers presented above, the lateral crystallite size can be calculated to  $\sim 4.5$  nm for films on Fe(110), whereas for Fe(001), a slightly larger size of

$\sim 6$  nm was found.<sup>27,28</sup> Therefore the passive film is best described as a nanocrystalline material. In the case of passive films on Ni(111) in sulfuric acid, slightly larger crystallite sizes of  $\sim 8$ – $10$  nm were found.<sup>31</sup>

Even with the use of SR, XRD is limited to particles or domain sizes of at least 2–3 nm to yield a measurable diffraction pattern in the sense of the Bragg equation. Thus, particles or domains with smaller size will appear as X-ray amorphous in an XRD experiment and will not reveal any sharp Bragg reflexes. In conclusion, XRD is an excellent method for very detailed information on crystalline structures, although in practice, the interpretation of the measured diffraction patterns may be very complicated.

### 2.31.7.2 X-ray Reflectivity

Due to the large penetration depth of hard X-rays in matter, X-ray techniques are in general not surface sensitive; that is, they are not suited for the investigation of surface phenomena such as passive oxide film formation, adsorption, corrosion, etc. without any special precautions. However, the whole spectrum of X-ray analytical methods (e.g., XAS, XRD, X-ray fluorescence, X-ray topography) can be made surface sensitive using the grazing incidence geometry, which is schematically shown in the insert of Figure 18. The energy dependent index of refraction  $n(E)$  in the

**Figure 18** X-ray penetration depth  $z_0$  for metallic silver and silver oxide  $\text{Ag}_2\text{O}$  at  $h\nu = 25\,200$  eV, as a function of incidence angle. The critical angle is  $\approx 0.13^\circ$  for Ag, and  $\approx 0.11^\circ$  for  $\text{Ag}_2\text{O}$ . In the insert, a schematic presentation of the grazing incidence geometry is given: the refracted beam is diffracted toward the surface.

hard X-ray regime is given by eqn [16],

$$n(E) = 1 - \delta(E) - i\beta(E) \quad [16]$$

where  $\beta$  and  $\delta$  are small positive quantities. Depending on the material and the photon energy, typical values for  $\beta$  and  $\delta$  range from  $\sim 10^{-4}$  to  $10^{-8}$ . The absorptive correction  $\beta$  is proportional to the linear absorption coefficient  $\mu$ , through  $\beta = \lambda\mu/4\pi$ . Therefore, condensed matter is optically thinner than vacuum, and X-rays entering into the samples surface are refracted away from the surface's normal, as indicated in the insert of Figure 18. The application of Snell's law of refraction, which has the same form as in the visible spectral range (eqn [17]),

$$n_1 \cos \phi_1 = n_2 \cos \phi_2 \quad [17]$$

suggests the existence of a glancing angle  $\phi_c$ , the critical angle, for which  $\phi_2 = 0$ . Assuming  $n_1 = 1$  for vacuum,  $\phi_c$  can be calculated from  $\cos \phi_c = n_2$ . If the absorption term  $\beta$  can be neglected, a simple calculus leads to  $\phi_c \approx (2\delta_2)^{1/2}$ . Typical values for  $\phi_c$  are  $0.39^\circ$  for Cu and  $0.22^\circ$  for Al for 8600 eV photon energy, so that total reflection can only be observed for grazing incidence angles below  $0.5^\circ$ .<sup>32</sup> In this case, there is no X-ray wave propagation inside the material, and the electric field amplitude within the sample is damped exponentially with depth. The decay constant, that is, the penetration depth  $z_0$ , amounts to only few nm below the critical angle. This relation is illustrated in Figure 18 for Ag and Ag<sub>2</sub>O, where a value of  $\sim 2$ – $3$  nm is obtained below the critical angle, while a steep increase is observed above  $\phi_c$ . This behavior generally leads to a steep decrease of the XRR for angles larger than the critical angle, and a detailed evaluation of such angle dependent specular reflectivities may yield the density and the surface roughness of the material.<sup>32</sup> In the case of a thin film on a substrate, the X-rays that have penetrated the surface layer will be reflected at the inner interface and interfere with those beams that have been reflected at the outer side, that is, the air–vacuum surface, leading to a systematic variation of the measured reflectivity profiles. Their detailed analysis yields to the thickness of the film and the roughness of the inner interface, in addition to the densities of the film and the substrate and the surface roughness.<sup>32</sup> Without going into great detail, it should be mentioned here that multilayered film structures can be treated and analyzed in a straightforward manner, so that specular reflectivity measurements are ideal tools for the *in situ* observation of electrochemical growth of oxide and passive layers and their reduction.<sup>33</sup> In Figure 19,

specular reflectivity profiles recorded in the course of several oxidation–reduction cycles of a thin film Cu electrode in borate buffer (pH 8.4) are shown for a photon energy of 7700 eV ( $\lambda = 0.148$  nm). The incidence angle scale was transferred to the transferred momentum ( $Q_z$ ) scale by  $Q_z = 4\pi/\lambda \sin \phi$  (see also Figure 16). As can be seen in Figure 19, the reflectivity profiles change considerably upon the oxidation and reduction of the Cu electrode. For example, the thickness oscillations are much more pronounced for the

**Figure 19** A series of specular X-ray reflectivity profiles measured *in situ* in the course of the anodic oxidation and reduction of a Cu thin film electrode in borate buffer solution (pH 8.4). The measurements were performed at the potentials indicated, and the curves are vertically offset for easier visualization. Reproduced from You, H.; Melendres, C. A.; Nagy, Z.; Maroni, V. A.; Yun, W.; Yonco, R. M. *Phys. Rev. B* **1992**, 45, 11288–11298, with permission from American Physical Society.

reduced electrode, while only weak thickness fringes can be identified in the case of the oxidized sample, which are the first indication of an increased roughness at the interface to the electrolyte. Moreover, it can already be seen in these raw specular reflectivity data that the original state of the electrode is not recovered after completion of several oxidation/reduction cycles. The quantitative analysis of the presented data allows a microscopic access to the processes at the electrode/electrolyte interface. For example, the surface roughness of the electrode/electrolyte surface is  $\sim 1.1$ – $1.2$  nm in the reduced state prior to the oxidation, while it increases to  $\sim 2.5$  nm in the fully oxidized state. After a completed oxidation–reduction cycle, the electrode remains with an irreversibly increased roughness of  $\sim 1.6$  nm, which can be further increased by prolonged cycling between anodic oxidation and cathodic reduction conditions.<sup>33</sup> Such a behavior has been previously found for Cu and Ag electrodes in alkaline media using SEM and quartz microbalance techniques and is important with regard to surface enhanced Raman scattering (SERS). Furthermore, the increase of the oxide layer thickness with increasing potential at the expense of the thickness of the thin film metal electrode is evident. The thickness of the fully developed oxide layer on Cu amounts to  $\sim 3.0$  nm, in agreement with previous *ex situ* XPS, UPS, and ISS experiments<sup>5,10,16</sup> and *in situ* Raman spectroscopy.<sup>34</sup> However, the reduction is fully reversible, as the initial thickness of the metal layer is recovered after a complete oxidation–reduction cycle. Such a behavior can be anticipated from the cyclic voltammogram, where balanced anodic and cathodic charges were found. In conclusion, we would like to mention that specular XRR measurements can be used for the *in situ* investigation of gaseous oxidation and corrosion processes in a similar way.

### 2.31.7.3 X-ray Absorption Spectroscopy

The basic process underpinning XAS is identical to that of the XPS-technique, that is, an incident photon with sufficient energy is absorbed by an atom and excites a core electron to unoccupied levels (bands) or to the continuum. This excited atom can relax by filling the empty core level with an electron from a higher occupied core level. The energy difference of the involved electronic levels can be released as a photon or may lead to emission of an Auger-electron. XAS is governed by the details of this photon absorption process. In a XAS experiment, the absorption of X-rays within the sample is measured as a function

of the X-ray energy ( $E = h\nu$ ). More specifically, the X-ray absorption coefficient,  $\mu(E) = -d \ln I/dx$ , is determined from the decay in the X-ray beam intensity  $I$  with distance (sample thickness)  $x$ . Monochromatic radiation is used, the energy of which is increased to the point at which core electrons can be excited to unoccupied states close to the continuum. In **Figure 20**, an absorption spectrum of a gold metal foil is shown for an extended photon energy range. The experimental data show three general features: (1) an overall decrease in X-ray absorption with increasing energy; (2) the presence of sharp rises at certain energies called edges, which roughly resemble step-function increases in the absorption (i.e., K-, L-, and M-edges in **Figure 20**); and (3) above the edges, a series of wiggles or an oscillatory structure occurs which modulates the absorption typically by a few percent of the overall absorption cross section as can be seen in the insert of **Figure 20**. It should be already stressed at this stage that the availability of intense new synchrotron X-ray sources permits the investigation of highly dilute systems such as impurities or trace elements within an alloy, or adsorbates and thin films on a surface of a foreign substrate. This capability of the XAS-technique is important and somehow unique with regard to the investigation of corrosion processes, where the

**Figure 20** Schematic view of the absorption spectrum of a gold metal foil over a wide energy range. Steep increases of the absorption coefficient are related to the K-, L-, and M-edges, respectively. The inset shows the absorption at the Au-L edges on a magnified scale. The oscillatory behavior of the absorption coefficient  $\mu(E)$  above the edge, known as EXAFS, is clearly resolved at each of the L-edges. The extracted fine structure oscillations  $\chi(k)$  measured at the  $L_3$ -edge after the removal of the smooth background function  $\mu_0(E)$  are also displayed as a function of the photoelectron wave vector.

alloyed elements often have a dramatic influence on the resulting corrosion protection properties. Various alloyed elements of a specimen can be investigated separately by XAS due to their different X-ray absorbing edges. However, for the investigation of flat electrode surfaces, a simple transmission mode experiment is not adequate. Fluorescence mode detection and/or grazing incidence techniques are required, which are well suited even for samples in an electrochemical environment.<sup>22,24</sup>

The general decrease of  $\mu$  with  $E$  can be related to the well-understood quantum mechanical phenomenon of X-ray absorption by atoms, which can be described by Fermi's golden rule. As with the energy of fluorescence photons, the energy of the absorption edge is characteristic of the absorbing material and hence the measured edges are signatures of the atomic species present in a material. For example, for the transition metals Fe, Co, Ni and Cu, the K edges are located at 7112, 7709, 8333, and 8979 eV, that is, there is a separation of 600 eV between consecutive edges, while, for example, the Mo K edge is located at 20 000 eV. Each edge corresponds to a quantum-mechanical transition that excites a particular atomic core-orbital electron to free or unoccupied levels. The nomenclature for the X-ray absorption edges reflects the origin of the core electron; that is, K edges refer to transitions that excite the innermost 1s electron, while L edges are related to those of 2p<sub>3/2</sub> (L<sub>3</sub>), 2p<sub>1/2</sub> (L<sub>2</sub>), and 2s (L<sub>1</sub>) initial states. These transitions always occur in unoccupied states, that is, in states with an excited photoelectron above the Fermi energy leaving behind a core hole. In a solid, such a photoelectron generally has enough kinetic energy to propagate freely through the material and independent from the structure and the state of matter of the sample under investigation. From the change of the absorption coefficient at the edge, the concentration of the respective element can easily be calculated (see, e.g., Ref. 20). For example, if a metal is corroded and dissolved in an electrolyte, the specific absorption of the element of interest within the electrolyte can be used for the analysis of soluble corrosion products in the active, passive or transpassive state of a metal or the selective dissolution of a single element in a multielement specimen such as an alloy.

Similar to an XPS experiment, the exact energy of the absorption edge is a sensitive function of the valency of the excited atom. In general, a shift of the absorption edge toward higher photon energies is observed as the chemical valency of the absorber atom is increased, i.e., with increasing oxidation

state.<sup>35,36</sup> In many cases, a more or less linear shift of the edge with typically 1–3 eV per unit of the valency can be found in the literature for different elements. This effect provides an easy access to determine the valency of a selected element (see, e.g., Refs. 35–37) even for trace elements in complex systems. In addition, in some special cases, there are also features in the absorption spectrum below the edge. These so-called pre-edge peaks can be attributed to transitions from the excited photoelectron into unoccupied electronic levels of the sample, that is, an X-ray absorption spectrum probes the density of unoccupied states of the absorbing element.

The detailed structure of the absorption coefficient within ~50 eV above the edge is referred to as near edge X-ray absorption fine structure (NEXAFS) or X-ray absorption near edge structure (XANES). Besides the above mentioned transitions into unoccupied states, the near edge structure also involves transitions of the photoelectron into the continuum, that is, into states above the vacuum level. In the latter case, the photoelectron has a low kinetic energy and accordingly a large (inelastic) mean free path (see, e.g., Ref. 13), so that it can undergo multiple scattering events.<sup>38</sup> The shape of the edge is thus highly sensitive to both the valency and the coordination of the absorbing atoms, including also the angular arrangement of the neighboring atoms. Although the complexity of the involved processes makes a full theoretical treatment very difficult, it is currently possible to calculate near edge X-ray absorption spectra on an *ab initio* basis, that is, based on the assumption of a model structure.<sup>38</sup> This approach works quite well for molecules and complexes – which is an interesting feature for the investigation of corrosion products within the electrolyte as shown in Ref. 37. However, for crystalline materials it is still a quite challenging task to fit an experimental spectrum using *ab initio* calculations since the theory of XANES is not fully quantitative and requires several physical considerations.<sup>38</sup> Thus, for the practical analysis the near edge spectra are most commonly used as fingerprint techniques. Edges are collected for a number of standard compounds with known valence and crystal structure and these are compared to the spectra of the actual samples. Certain compounds such as Cr<sup>6+</sup> or Mo<sup>6+</sup> give rise for distinct pre-edge peaks, so that these species can be identified qualitatively and quantitatively. For the application of fingerprint techniques to electrochemical probes, see for example, 24, 37. As an example for the application of XANES spectroscopy in

corrosion research, we present a study dealing with the initial stages of high temperature corrosion of Y-implanted Fe–Cr steels.<sup>39</sup> This study intends to examine the so-called ‘rare-earth effect.’ It is well-known that the presence of a small percentage of active elements, especially rare-earth elements, may have a beneficial effect on the properties and the adherence of protective scales to the substrate. In the present experiment, the rare earth element was inserted into the Ni–Cr alloy by means of 200 keV Y<sup>+</sup>-ion implanting, and the resulting samples were oxidized at 700 °C in a dilute oxygen atmosphere (1% O<sub>2</sub>, 99% Ar) for varying times. In **Figure 21**, grazing incidence XANES spectra acquired from the as-implanted sample and samples oxidized for different times are compared with the reference spectra from metallic Y and Y<sub>2</sub>O<sub>3</sub>.<sup>39</sup> A progressive oxidation of the samples is observed as the oxidation time increases, as directly evidenced by the shift of the absorption edge toward increasing energy values. Furthermore, after ~2 min of oxidation, the obtained spectra closely resemble those of yttria Y<sub>2</sub>O<sub>3</sub>. A more detailed investigation of the extended X-ray absorption structure suggests that the formed crystallites are of nanosize, and parallel XRD experiments revealed

**Figure 21** Near edge X-ray absorption spectra at the Y K-edge of a Y-implanted Ni–20Cr alloy in the as-prepared state as well as after oxidation in a gas atmosphere of 1% O<sub>2</sub> in Ar at 700 °C for 1, 2, and 8 min, respectively. (Metallic Y and Y<sub>2</sub>O<sub>3</sub> reference spectra are also shown). Reproduced from Gibson, P. N.; Crabb, T. A. *Nucl. Instrum. Methods B*, **1995**, 97, 495–498.

that the crystallization is *initiated* at the interface between the oxide scale and the bare alloy, proving in this case the positive effect of the dispersed rare earth element on the formation of a well ordered oxide.<sup>39</sup>

The third general feature in XAS spectra are the oscillations of the absorption coefficient which are visible up to ~1000 eV above the edge. This so-called extended X-ray absorption fine structure (EXAFS) originates from scattering of the emitted photoelectrons by neighboring atoms. The photoelectron, which is ejected from the absorbing atom, can be described as a propagating electron wave with a wave vector  $k$  and a de Broglie wavelength  $\lambda$  (eqn [18]):

$$k = \frac{\sqrt{2m(E - E_0)}}{\hbar}, \lambda = 2\pi/k \quad [18]$$

$E$  is the actual photon energy,  $E_0$  the edge energy,  $m$  the electron mass,  $\hbar = h/2\pi$  and  $h$  is Planck's constant. This wave can be scattered by neighboring atoms, so that the outgoing wave interferes with the backscattered wave. Depending on the distance,  $r_j$ , to the scattering atoms and the wavelength of the photoelectron, this interference can be constructive or destructive, resulting in an increase or a decrease of the absorption coefficient by some few percentage points. This phenomenon was first theoretically described by the short range order theory developed by Sayers, Stern, and Lytle.<sup>40</sup> In contrast to the near edge structures in the absorption coefficient, the theory of the EXAFS is today well understood with acceptable tolerances from the experimental results.<sup>38</sup> The EXAFS spectrum  $\chi(E)$  above a given absorption edge is defined as the oscillatory part of the X-ray absorption:

$$\chi(E) = \frac{\mu(E) - \mu_0(E)}{\mu_0(E)} \quad [19]$$

$\mu(E)$  is the energy dependent absorption coefficient, and  $\mu_0(E)$  is the smoothly varying, atomic-like background absorption.  $\mu_0(E)$  contains all the contributions from other edges and other elements and their absorption edges within the sample. According to the plane-wave concept and the single-scattering approximation, the EXAFS oscillations  $\chi(\kappa)$  can be expressed by eqn [20]:

$$\chi(\kappa) = \sum_j S_0^2 N_j \frac{|f_j(k)|}{\kappa r_j^2} \sin(2\kappa r_j + \delta_j(k)) e^{-2r_j/\lambda(k)} e^{-\sigma_j^2 \kappa^2} \quad [20]$$

$N_j$  is the coordination number of the central atom in the  $j$ th shell,  $f_j(k)$  the backscattering amplitude,  $\sigma_j$  the mean relative displacement of the atoms in the  $j$ th

shell, and  $\delta_j$  a phase shift associated with the interactions of the photoelectron wave with the potential of the absorbing and the backscattering atoms. Since different backscattering atoms have their own characteristic backscattering phases and amplitudes, EXAFS enables identification of the nature of the atoms in each coordination sphere around the absorbing atom. In contrast to XRD, EXAFS is very sensitive toward light backscattering atoms, which justifies its use for the investigation of, for example, oxides and passive layers. The disorder  $\sigma^2$  is partly due to thermal effects, which cause all the atoms to oscillate around their equilibrium positions. Effects of structural disorder are similar, giving an additional contribution to  $\sigma^2$ . Both effects can be separated by means of temperature dependent measurements. As a consequence of the  $1/r_j^2$  dependence of  $\chi(k)$  and the limited mean free path of the photoelectrons characterized by  $\lambda(k)$ , EXAFS is useful in providing information about the local short-range order around the absorbing atom, that is, the fine structure contains precise information about the local atomic structure around the atom that absorbed the X-rays. The structural information is typically obtained by Fourier-filtering of the experimental  $\chi(k)$  data into distance-space, giving a radial distribution function from which coordination numbers, interatomic distances, and the local disorders are determined.<sup>40</sup> Similar to the XANES, this turns out to be a unique signature of a given material, since it depends on both the detailed atomic structure and its vibrational properties. For this reason, EXAFS has become an important probe especially for disordered materials, where XRD can hardly be applied due to the absence of any long range order correlations. A complete data analysis comprises the separation of the individual shells contributing to the radial distribution function, and the fitting of these peaks with phases and amplitude functions.<sup>41</sup>

In this contribution, we will not show a detailed data evaluation, but only focus on the main features of EXAFS. As an example, in Figure 22, we show the *in situ* evolution of the EXAFS at the Ni K-edge (8333 eV) of a metallic Ni-layer on an  $\text{Al}_2\text{O}_3$ -substrate during the formation of a spinel-type oxide in an  $\text{O}_2$ -containing atmosphere at elevated temperatures.<sup>42</sup> First, the thin Ni film was oxidized to NiO at 700 °C, and the resulting X-ray absorption fine structure of this Ni-oxide thin film is similar to that of the crystalline NiO-reference material, as can be seen in Figure 22. In a second oxidation step at an elevated temperature of  $\sim 1000$  °C, this NiO-layer interacts with the Al-oxide substrate, and a spinel-type

**Figure 22** EXAFS of a Ni thin-film sample on a single crystal  $\text{Al}_2\text{O}_3$  substrate after (a) initial deposition, (b) 20 min in 60 mbar  $\text{O}_2$  at 973 K, and (c) additional 9 h oxidation at 1273 K. For comparison, spectra of metallic Ni and crystalline NiO and  $\text{NiAl}_2\text{O}_4$  spinel are also presented. Reproduced from d'Acapito, F.; Davoli, I.; Ghigna, P.; Mobilio, S. *J. Synchrotron Rad.* **2003**, *10*, 260–264.

$\text{NiAl}_2\text{O}_4$ -layer is formed as can be deduced by comparing this high temperature spectrum with that of the related spinel reference material.<sup>42</sup> In a similar way, the oxidizing effect of elevated temperatures on high- $T_c$  superconductors has also been proven, showing clearly the further oxygenation of the superconductor as well as the appearance of new phases.<sup>43</sup> It is important to mention here that several *in situ* EXAFS studies have also dealt with electrochemically formed passive layers on various metals and alloys (see Refs. 24, 27, 28, 37, 44). Finally, due to the fact that XAS experiments are element specific and not restricted to investigations of crystalline materials (such as XRD studies), it is possible to investigate in detail the structure and the chemical state of corrosion products dissolved in the electrolyte in front of a corroding electrode.<sup>20,37</sup> The use of the state of the art detectors and stable monochromators also enables the investigation of highly dilute solutions, and time resolved investigations are easily possible, so that the change in concentration in solution can be followed in tandem with changes in the structure of the solid.

### 2.31.8 Glow Discharge Optical Emission Spectroscopy (GDOES)

If a sufficiently high voltage is applied, a GD can be generated between two physically separated

electrodes in a gas filled vacuum vessel with a pressure of typically 10–1000 Pa. Depending on the gas type and pressure, the distance of the electrodes and the applied voltage, electrical currents, and characteristic light emissions are observed. We will only focus on the most relevant points here; for more detailed information on the fundamentals of GDs, the reader can refer to the literature, for example, Ref. 45. As a result of the physical processes, GD plasma shows several luminous and dark regions. For analytical use of the GD, the optical emission in the luminous regions are studied and analyzed quantitatively. It is also essential that the cathode (sample under study) is exposed to a bombardment of ions and fast neutral species from the plasma, and therefore, the cathode is eroded and cathode material is released into the gas phase continuously – this effect is known as cathode sputtering. This sputtering of the cathode is the basis for analytical exploitation of GD. The sputtered species from the sample arrive in the plasma where they are subject to ionization and excitation. If the corresponding ions are measured in a mass spectrometer, they can be identified quantitatively. This method is called glow discharge mass spectrometry (GDMS) in literature. On the other hand, the excited atoms emit characteristic photons during their deexcitation which in principle allow their identification, if they are detected with an optical spectrometer. This technique is called GDOES. It should also be mentioned here that the sputtered

atoms and ions can also be excited with an external light source for atomic absorption (GDAAS) or fluorescence (GDAFS) spectroscopy. Given that the sample is continuously eroded, a depth profiling of the sample is possible, if the erosion rate is calibrated properly. In contrast to other depth profiling techniques, matrix effects only play a minor role here because of the spatial separation of the sputtering and excitation of the sputtered atoms, as well as their dilution in the plasma. Using the Monte-Carlo simulation techniques, it is possible to calculate the profile of the sputtered crater on the sample, where reasonable agreement to the experiment was found for direct current GDs. These simulations also show that a homogeneous electrical field distribution in the active (sputtering) region is required to ensure that the sample surface is evenly eroded, resulting in a sputter crater with a nearly flat bottom. Only in this case, a well resolved depth profile of the sample can be obtained. It is noteworthy to mention here that for analytical GDs argon is most commonly used as the discharge gas, in order to avoid chemical reactions of the sputter gas with the sample and the system. In addition, a small but continuous flow is applied to ensure a clean atmosphere during the process of analysis.

A schematic representation of a GDOES analytical system is shown in Figure 23. The hollow anode configuration is composed of a grounded metal tube. An appropriate window confines the vacuum vessel on one side, while the flat sample closes the

**Figure 23** Schematic representation of a spectrometer for glow discharge optical emission spectroscopy (GDOES). The sample, cathode, is placed in a hollow, as shown, in an expanded view in the insert. Ions from the plasma are accelerated against the sample, and material is eroded and subsequently diffuses into the plasma. Here excitation of these atoms may occur, leading to the emission of characteristic photons during relaxation to the ground state. These optical emissions of the plasma are focused onto the primary slit of a grating spectrometer, where the spectrum is analyzed by means of a grating spectrometer, and the spectral contributions of different species are detected by an array of photomultipliers.

discharge cavity on the other side. This way, sample introduction or change is easy, and the electrical power that is needed for ignition and maintenance of the plasma is simply supplied to the sample. The sample holder is water cooled in order to limit the heating of the samples. Usually, a quartz window is used because of its transparency for photons of lower wavelength.

In the case of a conducting (metal) sample, a regulated DC-voltage of typically some hundred volts is applied. As for sputtering, etching, and coating processes, however, the GD can also be energized by alternating radiofrequency (RF) fields in order to investigate in particular poor/bad or nonconducting samples.<sup>45</sup> Assuming the presence of a nonconducting sample, a DC-discharge would cause a positive charging of the cathode because of the recombination of positive ions and electrons coming from the near surface region of the sample. As a consequence, the potential drop between the two electrodes would decrease and the discharge would extinguish, within some few milliseconds, with a positive charge remaining on the sample. If the direction of the voltage is reversed, the same processes will occur, resulting in a decrease of the positive charge on the sample, which in this case acts as an anode until a negative charge is accumulated so that the discharge is stopped again. If the switching of the voltage polarity is repeated continuously with a high frequency, that is, RF with a power of typically up to  $\sim 30$  W, the discharge can be maintained continuously even for nonconducting samples. Using frequencies in the mega-Hertz range, the plasma with typical frequencies of the order of 1 kHz is not able to decay but will glow permanently. One may argue that the use of an RF-discharge could be disadvantageous for GDOES-investigations because the material of the hollow electrode will be sputtered as well and thus contribute to the measured optical emissions. However, due to the characteristic design of the two electrodes, the sputtered area on the sample is limited to some few square millimeter while on the other hand the area of the hollow tube exposed to electrons and ions is not restricted at all and can be extended as much as required by the size of the GD plasma, thus reducing the related contributions accordingly.

The spectrometer displayed in [Figure 23](#) employs a concave grating that is fixed in the Rowland geometry, and the light emissions from the GD are focused onto the entrance slit of the spectrometer using a lens of suitable focal length. Several photomultiplier tubes are mounted at well defined positions on the Rowland

circle for light detection related to some few specific excitation lines, as it is not possible to measure a full spectrum in this configuration. However, due to the fast erosion of the samples, it is important to make use of an extremely fast and reliable detection method for the excited photons. State of the art systems employ up to 60 individual detectors in parallel. The use of solid state detectors, charged coupled devices or photo diode arrays have become a common alternative to photomultiplier tubes. These detectors allow the acquisition of the entire spectrum, or at least a large portion of it, but are usually slower than photomultiplier tubes and therefore not suitable in those cases where extremely short acquisition times are required, for example, for the analysis of adsorbates or very thin surface films. Light elements such as hydrogen, carbon, nitrogen, oxygen, or sulfur have important spectral lines in the vacuum ultraviolet (UV) region with wavelengths below  $\sim 200$  nm. For example, oxygen species are in many cases identified using an oxygen emission line at 130.2 nm. Spectrometers in this spectral range are usually operated under vacuum, or at least a purged nitrogen atmosphere to obtain a sufficient transparency in this spectral range.

GDOES, as an analytical technique, was introduced by Grimm in 1968 with first applications being the determination of the bulk atomic compositions of metal alloys.<sup>46</sup> The capabilities of GDOES for surface analytical studies was proven a few years later with oxidation studies of steels being one of the first areas of research interest. In a depth profiling experiment, the intensities of the spectral lines of interest are measured as a function of the sputter time. For a quantitative analysis, these have to be converted to an analyte concentration and a sputter depth. Although the detection limits for GDOES are generally small with typical values in the range of 1–10 ppm, an exact determination of atomic concentration and film thicknesses is in many cases not straightforward and the use of more sophisticated calibration procedures for example, using certified materials in a wide range of elemental compositions, is recommended. Furthermore, spurious hydrogen in the plasma, either from a contamination of the plasma gas or the sample, may affect the measured concentrations of the analytes and have to be corrected accordingly. Nevertheless, in combination with the numerous efforts that have been made for quantitative modeling and understanding of GD-plasmas and sputtering for analytical purposes, and because of its easy use, GDOES has become an

interesting and important method for routine depth-profiling analysis in a wide range of applications, including corrosion phenomena.

Corrosion protection coatings – in particular on steel – are an important topic. The depth profiling capabilities of GDOES give a fast and direct access to a simple determination of the composition of the coating as well as its thickness. This is of special importance in those cases where the coating contains the same chemical elements as the underlying steel, such as for Fe/Zn-coating on iron based steels. For industrial applications, it is in many cases important to know the structure and the composition of a material in order to accomplish reproducible physico-chemical properties such as, mechanical elasticity and plasticity, or corrosion resistance of metal sheets. These properties are often influenced by the pre-treatment of the metal, such as milling or hot-rolling which alter the microstructure and the composition of the metal significantly. Depending on the details of the processing conditions, trace elements, impurities, or rolled-in oxide particles are located especially in the near surface region of the metal. In [Figure 24\(a\)](#), GDOES depth profile of a hot-rolled steel surface is presented.<sup>47</sup> As can be seen, the oxide layer on the steel has a rather complex substructure, and even the alloyed elements Mn and Si are detectable, although their atomic concentrations are only in the 1% range. Besides the near surface region of some 10 nm, where Si is significantly enriched, the outer oxide scale has a lower Fe-content compared to the inner part of the duplex layer, which contains significantly more iron. The manganese concentration is smaller in the outer layer, and increases in the inner layer, but it is still depleted compared to the bulk concentration. While

the entire oxide is almost free of Si and C, both elements are significantly enriched at the interface between the oxide and the bulk material.

In a similar manner, GDOES has fostered our understanding of high temperature corrosion processes and materials. Very recently, first studies on materials and coatings that are used in biological environments and biocorrosion have been published. The thickness and the composition of passive oxide layers were determined using GDOES for a variety of different materials and for various electrochemical environments – here the most important aspect of GDOES is its easy operation and data interpretation. This is also true for samples of archeological interest, where GDOES can easily be applied to conducting as well as to nonconducting samples such as, ancient bronzes, ceramics, pottery, etc., and GDOES may give information which is important for the conservation of such objects.

In conclusion, when considering GDOES for a practical application, one should always have in mind that the recorded depth profiles are destructive, which is sometimes critical for example, in the case of archeological objects. Furthermore, GDOES is always an *ex situ* method, that is, it relies on the assumption that the sample is not affected or altered by the transfer to the spectrometer and the bombardment with electrons and ions, which seems to be true for metals and alloys. Compared to UHV-techniques such as XPS or SIMS, GDOES is not very time-consuming, and the repetition of each experiment allows one to apply statistical techniques to the results, for example, to elemental concentrations or thickness *values*, which is again important for industrial applications. On the other hand, however,

**Figure 24** GDOES depth profile of an oxide layer on hot-rolled carbon steel. The concentration scale for each of the elements is given in relation to the following values: 100% for Fe, 50% for O, 0.5% for Mn, 0.2% for C, and 2% for Si. Reproduced from Weiss, Z.; Musil, J.; Vlcek, J., *Fresenius J. Anal. Chem.* **1996**, 354, 188–192.

GDOES is not able to specify the binding state of an element, that is, GDOES is not able to distinguish between a metal cation and the reduced metal. Thus, it is useful to combine GDOES with other techniques in order to strengthen the conclusions drawn.

### 2.31.9 Infrared Spectroscopy

Infrared spectroscopy applies electromagnetic radiation of wavelength  $\lambda$  or wave number  $\tilde{\nu}$  of the middle-IR range ( $\lambda = 2.5\text{--}50\ \mu\text{m}$ ,  $\tilde{\nu} = 4000\text{--}200\ \text{cm}^{-1}$ ) to a sample. Typically, the near-IR range ( $\lambda = 0.8\text{--}2.5\ \mu\text{m}$ ,  $\tilde{\nu} = 13\,000\text{--}4000\ \text{cm}^{-1}$ ) or the far-IR range ( $\lambda = 5\text{--}1000\ \mu\text{m}$ ,  $\tilde{\nu} = 200\text{--}10\ \text{cm}^{-1}$ ) are of minor importance for this spectroscopic method. The absorption of IR-radiation in the middle range by a sample leads to excitation of vibrational modes of its molecules as a whole (fingerprint region,  $\tilde{\nu} = 600\text{--}1200\ \text{cm}^{-1}$ ) or of characteristic groups such as C=O and O–H (group frequency region,  $\tilde{\nu} = 1200\text{--}3600\ \text{cm}^{-1}$ ). The excitation of vibrations is controlled by selection rules. For IR absorption, the dipole moment should change with the oscillation mode. Therefore, polar groups like C=O are IR-active. If, however, the changes in the dipole moment compensate internally within a molecule, the IR mode is inactive, for example, the symmetric stretch of O=C=O. The asymmetric stretching and the bending vibrations of O=C=O are IR-active. We note that the selection rules for Raman Spectroscopy depend on the polarizability of groups and molecules. Under the selection rules for Raman, the symmetric stretching of the O=C=O molecule, which has an inversion center, is active, whereas the asymmetric stretching and the bending mode are Raman-inactive. Thus, IR and Raman can give complimentary results.

An IR spectrometer usually has a strong light source like a Nernst Glower, which is an electrically heated rod of rare earth oxides, or a Globar, a heated rod of silicon carbide. A very intense IR source is SR. In this case, polarized light of high intensity is also available.

A more conventional IR spectrometer uses a monochromator, separating the incoming polychromatic radiation into its components and thus taking sequentially a wavelength dispersive spectrum. A Fourier transform IR (FTIR) spectrometer uses a Michelson Interferometer which creates an interferogram due to the different optical path length of the two interfering beams. Its Fourier transform leads to an IR spectrum. The advantages of this approach are

a much better signal to noise ratio and the short time required to record a spectrum. Here the whole spectrum is obtained in parallel, rather than sequentially, with no loss of radiation at the entrance and exit slits of a monochromator. A spectrum may be obtained within a second, and thus it is possible to follow the kinetics of corrosion processes. An additional advantage of FTIR spectroscopy is the high spectral resolution of  $0.1\ \text{cm}^{-1}$ .

A variety of detectors are utilized in IR spectroscopy, based either on thermal or photonic response. Thermal detectors are IR absorbers that measure the produced heat via thermocouples, or bolometers, which measure the change of heat via the resistance change of a platinum wire. Pyroelectric detectors are also employed. They use chopped IR light, which changes the polarization of a condenser whose capacity is a measure of the absorbed radiation and the thereby produced heat. They have the advantage of suppressing background radiation efficiently. As regards photonic detectors, low band gap semiconductors such as  $\text{Cd}_x\text{Hg}_{1-x}\text{Te}$  (CMT) are typically used, where the incoming IR radiation excites electrons from the valence to the conduction band leading to photocurrents which are a measure of its intensity. CMT detectors are very sensitive and have a fast response so that they are widely used for FTIR spectrometers.

IR spectroscopy is routinely employed by synthetic chemists in the transmission mode, with specimens pressed as pellets often in KBr as an IR transparent medium or in solution with appropriate organic solvents. In aqueous corrosion and electrochemistry, the chemistry of a metal surface and its changes with the corrosion process are of decisive importance. Therefore, one needs to investigate the surface preferably in its natural environment. Two main problems arise. First, water strongly absorbs IR-radiation. Therefore, the transmission path in water should be avoided or made as short as possible. Furthermore, thin films or absorption layers are often of interest and not the substrate metal or the bulk electrolyte and the information should come from the electrode/electrolyte interface. Therefore two main approaches are used in electrochemistry and corrosion science, namely attenuated total reflection spectroscopy (ATR) and IR-Reflection-Absorption Spectroscopy (IRAS and IRRAS).

#### 2.31.9.1 Attenuated Total Reflection

In ATR spectroscopy, the IR beam travels through a crystal such as Ge or ZnSe with total reflection at its

interfaces, that is, the angle of incidence, measured against the normal surface, is above its critical value of total reflection. One surface of the ATR crystal may be covered with a very thin metal layer which then is exposed to the electrolyte. Although the radiation is totally reflected, the electrical field vector penetrates the metal and samples the electrode–electrolyte interface with a depth of  $\sim 0.1\text{--}5\text{ }\mu\text{m}$  (evanescent wave). It thus picks up the IR spectrum of adsorbed molecules and thin layers and may follow changes at the interface even for well controlled electrochemical conditions with a potentiostat and counter and reference electrode.

### 2.31.9.2 IR Reflection Absorption Spectroscopy

In IRAS, the IR-beam strikes the specimen surface from the front side at grazing incidence, i.e., at a large angle relative to the surface normal. This geometry permits an intense interaction of the beam with the electrode–electrolyte interface. For IR radiation polarized parallel to the plane of incidence (containing the incoming beam and the surface normal), that is, p-type radiation, the electrical field vector changes in the direction of the axis of at least partially perpendicularly oriented molecules and thus gives its characteristic interaction and absorption lines. For perpendicularly oriented, s-type radiation one does not get a signal, for due to a  $90^\circ$  phase shift during reflection it cancels with the incoming radiation. These surface selection rules lead to an IRAS-signal for those molecules oriented on the surface with a component of a changing dipole moment in the direction of the normal surface. These characteristics permit one to distinguish between the randomly oriented molecules within the electrolyte and those adsorbed with a characteristic orientation at the metal surface. IR spectroscopy may also contribute to the monitoring and understanding of atmospheric corrosion.<sup>48</sup> In this case, the electrolyte is a thin water containing film and thus does not cause too many problems for the application of the method.

### 2.31.10 Summary

This chapter describes the most important surface analytical methods which provide information on the chemistry and structure of corroding surfaces and surface layers. Many methods work in vacuum, and one should be aware that the specimen has lost the contact with its environment and the electrode

potential for the case of electrochemical corrosion systems. However, such broad and valuable information is urgently needed for an understanding of surface reactions and corrosion phenomena. It has been shown by numerous detailed studies that the results follow the systemically changed experimental parameters, for more extensive studies, when one examines the reaction, free of artifacts. *In situ* methods are free of this problem, but they cannot replace the rich information provided by the methods functioning only in vacuum. Generally, it is the combination of many methods which ensures understanding and a correct interpretation of the reactions and their mechanisms. XPS is a soft method and gives excellent data on the chemistry at the surface. AES allows a high lateral resolution, which is extremely important if localized corrosion phenomena occur. ISS may improve the depth profiles of thin films, and RBS will give a detailed insight into reactions on thick films, however, with a poor depth resolution of  $\sim 5\text{ nm}$  only. IR methods may give *in situ* information on the chemistry of the surface whereas XRD and XAS provide information on the structure, that is, the long range and the near range order of surfaces and surface films. In addition, *in situ* scanning tunneling microscopy and atomic force microscopy give exact information on their structure. Thus, all these methods supply details of the characteristics and the reactions occurring at a solid surface. Furthermore, some methods add spectroscopic information of the dissolved species in solution or in the gas phase like XAS in transmission mode. Table 1 summarizes the methods which have been discussed in this chapter and presents their advantages and disadvantages. A group might not have experts in all these methods, but laboratories may collaborate and thus the expertise and the equipment of the laboratories may be complementary. A collaboration will be useful when the different backgrounds of the scientists involved still allows them to communicate, which is a difficult task, as the methods range from corrosion and electrochemistry to surface physics and the application of SR facilities. It is often observed in science that different communities work parallel to each other, largely ignoring each other. However, the situation is improving. One requirement is crucial in all cases. The application of a sophisticated surface method to a system requires the full knowledge of its electrochemistry. Any study without a careful and reliable specimen preparation is useless. On the other hand, all these surface methods are needed to understand the surface reactions. Therefore, the surface physicist

should understand to some extent electrochemistry, corrosion, and materials science, and the corrosion engineer and electrochemist to some extent surface science and its related methods, which would be an excellent basis for a fruitful collaboration of experts.

### Glossary

**Adsorption** The first stage of interaction between a surface and its environment (gaseous or liquid), in which atoms or molecules are bound to the surface of a material.

**Corrosion** The degradation of a metallic material under the effect of the environment.

**Dissolution** The electrochemical reaction in which the metal is ionized and the cation thus formed goes into solution where it is hydrolyzed.

**Localized corrosion** Limitation of the corrosion of a metal surface to local areas.

**Passivation** The property of a metal to form a thin, continuous, compact, and adherent layer of oxide or oxyhydroxide (the passive film) at its surface that blocks the reaction of dissolution of metal atoms.

**Passivity breakdown** The local breakdown of the passive film.

**Pitting** The result of localized corrosion of passivated metal surfaces in local areas.

**Reconstruction** The change of atomic position when the surface of a material has a structure different from a bulk termination.

**Superstructure** The specific structure formed at the surface of a material.

### Abbreviations

**AFM** Atomic force microscopy

**CB** Conduction band

**DOS** Density of states

**ECAFM** Electrochemical atomic force microscopy

**ECSTM** Electrochemical scanning tunneling microscopy

**ECTS** Electrochemical tunneling spectroscopy

**SECM** Scanning electrochemical microscope

**SPM** Scanning probe microscopy

**STM** Scanning tunneling microscopy

**STS** Scanning tunneling spectroscopy

**UHV** Ultrahigh vacuum

**VB** Valence band

### Symbols

***d*** Distance between tip and sample surface (m)

***d<sub>z</sub>*** Deflection along the axis *Z* (m)

$e$	Charge of proton ( $1.6 \times 10^{-19}$ C)
$E_F$	Fermi level energy (eV)
$h$	Planck's constant ( $6.63 \times 10^{-34}$ J s)
$I$	Tunneling current (A)
$I_T$	Tip current (A)
$k$	Spring constant ( $\text{N m}^{-1}$ )
$m_e$	Mass of the electron ( $9.11 \times 10^{-31}$ kg)
$P_X, P_Y, P_Z$	Components of the piezoelectric scanner controlling $x, y, z$ position
$T$	Tunneling transmission probability
$U$	Intermolecular potential
$U_S$	Sample electrochemical potential (V vs. reference electrode)
$U_T$	Tip electrochemical potential (V vs. reference electrode)
$V_{\text{bias}}$	Bias potential between sample and tip (V)
$V_X, V_Y, V_Z$	Voltages applied to $P_X, P_Y, P_Z$ (V)
$X, Y, Z$	Orthogonal scan axes
$\phi$	Electron tunneling barrier height (eV)
$\kappa$	Tunneling decay constant ( $\text{m}^{-1}$ )
$\rho_s(E)$	Density of states of the sample at the energy $E$ ( $\text{m}^{-2}$ )
$\rho_t(E)$	Density of states of the tip at the energy $E$ ( $\text{m}^{-2}$ )

## 2.33.1 Introduction

Scanning probes microscopies (scanning tunneling microscopy (STM) and atomic force microscopy (AFM)) allow direct three-dimensional (3D) imaging of the surface structure and topography of materials at high resolution (atomic or molecular resolution). Their advent in the 1980s has opened up new prospects for the structural analysis of corroded surfaces, as these microscopes can be applied to both solid–gas interfaces under controlled environments (ultrahigh vacuum (UHV)) and to solid–liquid interfaces under electrochemical control. Moreover, time-resolved imaging allows the investigation of the dynamics of structure modifications produced by corrosion processes. The coupling of STM with spectroscopic measurements (scanning tunneling spectroscopy (STS)) provides information on a local scale on the electronic properties of surfaces.

This chapter describes the principles and operation of STM/STS and AFM and their electrochemistry implementation (ECSTM and ECAFM) for the analysis of corrosion processes at surfaces. Applications of ECSTM, ECTS, and ECAFM are illustrated by selected examples, emphasizing data obtained *in situ* at the solid–liquid interface on the anodic dissolution

of metals, the growth mechanism and structure of passive oxide layers and their electronic properties at the (sub)nanometer scale, and on the initiation of localized corrosion at the (sub)micrometer scale.

## 2.33.2 Scanning Tunneling Microscopy

This technique is unique in that it provides 3D real space images and allows localized measurements of geometric and electronic structures at high resolution. The first atomically resolved images were published in 1983.<sup>[1]</sup>

### 2.33.2.1 Principle and Operation

STM is based on tunneling of electrons between two electrodes separated by a potential barrier and biased by a voltage  $V_{\text{bias}}$  (Figure 1). Electrons within  $eV_{\text{bias}}$  of the Fermi level tunnel from the occupied states of the negatively biased electrode to the unoccupied states of the positively biased electrode. Assuming constant density of these electronic states, the tunneling current through the planar barrier increases linearly with  $V_{\text{bias}}$  and decreases exponentially with the barrier width  $d$  according to eqn. [1]

$$I \propto V_{\text{bias}} \exp(-2\kappa d) \quad [1]$$

where  $\kappa$  is the tunneling decay constant in the barrier, given by eqn. [2]

$$\kappa = \frac{2\pi}{h} \sqrt{2m_e\phi} \quad [2]$$

with  $h$  being the Planck's constant,  $m_e$  the electron mass, and  $\phi$  the tunnel barrier height. For electrons at the Fermi level,  $\phi$  is the work function of the negatively biased electrode. Since most work functions are 4–5 eV,  $\kappa \sim 1 \text{ \AA}^{-1}$  we find that for a bias of 0.1 V, a tunneling current of  $\sim 1.5$  nA can be observed for a separation between the two electrodes of  $\sim 0.9$  nm. The tunneling current drops by nearly one order of magnitude for every increase of 0.1 nm of the barrier width. A direct consequence of this exponential decay is that if one electrode is a tip terminated by an atomic asperity protruding by  $\sim 0.1$  nm at the apex (Figure 1),  $\sim 90\%$  of the current is spatially limited to this atomic asperity.

STM operation is based on precise control of the position of the tip with respect to the surface to be analyzed. The tip is placed on a tripod formed by three independent piezoelectric elements,  $P_X, P_Y, P_Z$ , controlled by the voltages  $V_X, V_Y, V_Z$  respectively (Figure 1). At a given bias voltage, the tip is scanned

**Figure 1** Schematic diagram of the scanning tunneling microscope and principle of electron tunneling through a biased potential barrier between sample and tip.

along the two lateral directions  $X$  and  $Y$  parallel to the surface, while a feedback loop constantly adjusts the tip vertical position along the  $Z$ -axis, so as to keep the current to a constant setpoint value chosen by the operator. This is the ‘constant current’ mode where  $\kappa d$  is kept constant. If the local work function  $\phi$  remains constant, a constant current corresponds to a constant distance  $d$  between tip and surface. The shape of the surface is then reproduced by the path of the tip. The values of  $V_Z = f(V_X, V_Y)$  are used to produce a 3D image of the surface most often displayed on the monitor, using a color or gray scale. The microscope can also be operated in ‘constant height’ mode with the feedback slowed down or switched off, but at the risk of tip damage, as the tip height is not adjusted.

The setpoint current used can vary from a few tens of picoamperes for poorly conductive surfaces to a few nanoamperes for metal or doped semiconductor surfaces. Bias voltages can vary from a few volts to a few millivolts. High quality tips can be prepared from tungsten or Pt–Ir wires by electrochemical etching.<sup>2</sup> The lateral (spatial) resolution of the instrument depends on the quality of tip preparation; it is, at best, typically  $\sim 0.1$  nm. The vertical (depth) resolution depends on the quality of the damping system used to isolate the instrument from external vibrations and on the precision of the control of the tip–sample distance; it is  $\sim 0.001$  nm at best. Most commercial instruments adhere to specifications that allow imaging at atomic resolution on reference samples.

### 2.33.2.2 Scanning Tunneling Spectroscopy

STM images also contain information on the local electronic structures of the surface and tip. According to the theory of STM,<sup>3</sup> the tunneling current is expressed as (eqn. [3])

$$I = \int_0^{eV_{\text{bias}}} \rho_s(r, E) \rho_t(r, E - eV_{\text{bias}}) T(E, eV_{\text{bias}}) dE \quad [3]$$

where  $\rho_s(r, E)$  and  $\rho_t(r, E)$  are respectively the density of states (DOS) of the sample and tip at location  $r$  and energy  $E$ , measured with respect to their individual Fermi levels.  $T(E, eV_{\text{bias}})$  is the tunneling transmission probability for electrons with energy  $E$  at applied bias voltage  $V_{\text{bias}}$ . For a fixed surface-to-tip distance and assuming to a first approximation, a constant  $\rho_t(r, E)$ , eqn. [4] can be deduced:

$$\frac{d \ln I}{d \ln V_{\text{bias}}} = \frac{dI}{dV_{\text{bias}}} \times \frac{V_{\text{bias}}}{I} \propto \rho_s(E) \quad [4]$$

It follows that  $\rho_s(E)$  can be extracted from measurements of the tunneling current as a function of the bias voltage applied to the tunneling barrier, that is, from tunneling spectroscopy  $I$ – $V_{\text{bias}}$  measurements.<sup>4</sup>

In tunneling spectroscopy (TS), quantitative information on surface electronic states is obtained using either modulation techniques or numerical techniques to measure  $dI/dV_{\text{bias}}$  at constant average tunneling distance as a function of  $V_{\text{bias}}$  at a single point of the surface. Such measurements can reveal structures in the surface density of states that can arise from critical points in the surface-projected bulk band structure or from true surface states associated with surface reconstructions, adsorbates, or ultrathin films formed on the surface. In scanning tunneling spectroscopy (STS), spectroscopic  $I$ – $V_{\text{bias}}$  measurements are combined with topographic measurements to extract laterally resolved information and map  $\rho_s(E)$  spatially. In the so-called current imaging tunneling spectroscopy (CITS) mode,  $I$ – $V_{\text{bias}}$  curves are recorded for every pixel of the topographic image with the feedback loop switched off in order to operate at a fixed surface-to-tip distance. The interest of corrosion science in these techniques is the possibility of acquiring laterally resolved chemical information on surfaces.

### 2.33.2.3 Application to the Solid–Gas Interface and Limitations

STM was originally designed for application at the solid–gas interface under UHV. The environmental control of the interface inherent to UHV allows one to

locally characterize, at the atomic scale, the surface structure of semiconductors, superconductors, and metallic materials, along with the modifications induced by the adsorption of atoms and molecules or by the deposition of nanoparticles. The technique is also widely used to study nanostructuring processes resulting from surface modifications. Operation at low temperature (down to 4 K) permits manipulation of atoms, molecules, and nanoparticles. Operation at high temperature (up to  $\sim 900$  K) limits space resolution due to acceleration of surface diffusion and thermal drift (uncontrolled variation of tip position with respect to the surface), and the time resolution due to activation of surface reactions.

For corrosion related studies, UHV-STM is mostly applied to study the initial stages of oxidation of metallic materials. The adsorption of oxygen on metallic materials has been the most studied topic. A review of data obtained on Cu, Ni, and Ag single-crystal surfaces has been published.<sup>5</sup> The technique allows one to determine the adsorption site of the adsorbate, the adsorbate superstructure including the reconstruction of the substrate possibly induced by adsorption, and the nature and role of defects.

The growth mechanism of the superstructure and surface diffusion can be studied by acquiring consecutive images from a selected area as a function of time (time-resolved imaging). However, the time resolution is of the order of several tens of seconds per image with most commercial microscopes and the application is restricted to relatively slow processes. Relatively fast physical processes can be slowed down by operating at low temperature, or alternatively, fast-scanning microscopes with a time resolution better than one second per image can be used. One such example of fast-scan STM applied to the solid–liquid interface is presented further on.

Time-resolved UHV-STM can also be applied to the solid–gas interface to study the mechanism of phase transformation from metals to oxides. The local nature of measurement is then most effective to characterize the sites of nucleation of the oxide phase and the role of surface defects, the growth mechanism of the nuclei until full coverage of the surface, and the structure of the oxide nuclei. STS can be combined with STM to locally characterize the oxide nuclei and the unmodified metallic areas.<sup>6</sup>

Because of its sensitivity to the topmost surface atomic layer only, STM is less effective in characterizing the structure of 3D films formed by oxidation at the surface of metals and alloys. Indeed, neither the inner structure of the film nor the buried metal–oxide

interface can be accessed, thereby preventing a detailed investigation of the mechanism of 3D growth of the oxide film. Rare exceptions of imaging of the buried metal–oxide interface have been reported when an ultrathin oxide film transparent to the tunneling electrons is formed on the metallic substrate.<sup>7</sup> In most cases, only the surface of the 3D oxide films can be characterized, including its atomic structure and nanostructural defects. However, the technique is well suited to locally characterize the reactivity of 3D oxide films and their resulting surface structural modifications. It has been applied, for example, to the interaction of water vapor with thermal oxide films of chromia grown on Cr surfaces<sup>8</sup> and alumina on NiAl surfaces.<sup>9</sup>

### 2.33.3 Electrochemical STM

STM was first applied in solution in 1986<sup>10</sup> and to corrosion studies in 1988.<sup>11</sup> A major difference with UHV operation is the decrease of the tunneling barrier height in solution. Experimental values ranging from 0.1 to 0.3 eV have been reported,<sup>12,13</sup> which is much smaller than the values of  $\sim 4$  eV for UHV operation.

#### 2.33.3.1 Electrochemical Implementation and Limitations

In ECSTM, the tip is immersed in the electrolyte and acts as a fourth electrode added to a conventional three electrode cell with working reference and counter electrodes (Figure 2). Charging of the double layer and electrochemical reactions take place at the tip–electrolyte interface. They generate capacitive and faradic currents at the tip that superimpose onto the tunneling current and must be minimized as they affect STM operation based on the measurement of the total tip current. The most effective minimization is obtained by reduction of the tip surface in contact with the electrolyte. This is done by covering most of the immersed portion of the tip by an insulating coating. Glass, epoxy varnish, silicone polymer, Apiezon wax, nail polish, or electrophoretic paint can be used. Well-prepared coatings will leave only  $\sim 10$   $\mu\text{m}$  or less, uncoated at the very end of the tip. Further minimization of the electrochemical currents at the tip is achieved by polarizing the tip in the double layer charging region (PtIr) or at the corrosion potential (W). This combined minimization allows one to decrease the electrochemical current to values of 50 pA or less, extremely small relative to the usual set-point current of 0.5–10 nA used in ECSTM,

**Figure 2** Schematic diagram of the four electrode cell used in ECSTM. RE is the reference electrode. CE is the counter electrode.  $U_S$  and  $U_T$  are electrochemical potentials applied to the sample and tip, respectively.  $I_S$  and  $I_T$  are the sample current and tip currents, respectively. For  $U_T > U_S$ , electrons tunnel from the occupied states of the sample to the empty states of the tip.

thus ensuring no interference with the functioning of the STM.

ECSTM, performed in a four-electrode cell, requires the use of a bipotentiostat that enables one to control independently the electrochemical potentials of the tip ( $U_T$ ) and sample ( $U_S$ ) relative to a common reference electrode. The bias voltage for STM operation is then given by the difference between  $U_T$  and  $U_S$ . The current resulting from the electrochemical reaction taking place at the sample–electrolyte interface is measured by the counter electrode, as in a conventional electrochemical cell.

There are limitations related to the local nature of the measurements. The high spatial resolution capability of the instrument, which provides the basis for the ability to image individual atoms or molecules, brings down the analyzed area to a tiny fraction of the total surface area (typically  $1 \times 1 \mu\text{m}^2$ ) or less. A correlation between STM-derived and electrochemical information (integrated over areas of  $1 \text{ cm}^2$  or less) is really meaningful only if the area probed by STM is representative of the whole electrode surface. Limitations can also arise from the possible interference of the tip with the electrochemical process at the working electrode surface. The close proximity of the tip can cause shielding effects for reaction at the sample–solution interface. An interference of sample and tip electric double layer is also possible.<sup>12,14</sup> Tip-induced corrosion processes can also occur.<sup>14,15</sup> Corrosion studies by ECSTM may also be limited by the small volume of the electrochemical STM cells. It is

indeed not possible to investigate the substrate modifications resulting from extensive corrosion processes as the observation of the substrate surface would be masked by redeposition of corrosion products.

Despite these limitations, ECSTM investigations can provide invaluable information, in particular molecular scale information, on the structural modifications related to corrosion processes such as the active dissolution and passivation of metallic surfaces as illustrated below, as well as the adsorption of corrosion inhibitors<sup>16</sup> or the reactivity of anodic oxide films determining the initial stages of localized corrosion of passivated metallic materials.<sup>17</sup>

### 2.33.3.2 Application to Corrosion Analysis at the Solid–Liquid Interface

The high resolution provided by ECSTM allows structural characterization of corrosion processes at the molecular level. This requires appropriate control of electrochemical conditions in order to minimize the rate of corrosion processes to a point compatible with the STM time resolution. In contrast with UHV-STM, corrosion reactions cannot be slowed down by operating at low temperatures because of the liquid environment, but electrochemical potential can be used to control the reaction kinetics. High resolution ECSTM also requires high quality of surface preparation and control, that is, atomically flat surfaces of well-defined structure. This can be achieved with single-crystals of known orientation whose surface has been appropriately prepared to have a terrace and step topography.

#### 2.33.3.2.1 Active dissolution of metals

ECSTM is very effective to study *in situ* the active dissolution of metals because the surface is free of passivating oxides and for pure metals, the electrode surface remains terminated by an atomically flat terrace and step topography during the corrosion process. This is a very favorable situation for atomic-scale imaging of dynamic processes at surfaces. Investigations can focus on the structural modifications of atomically flat surfaces resulting from adsorption of anions in the double layer potential region preceding the onset of dissolution and on the dissolution of metal atoms at specific sites. The formation of well-ordered superstructures, more corrugated than the metallic lattice, facilitates high resolution ECSTM imaging of the surface structure. For alloys,

dealloying can be studied. The dynamics of these processes can be studied by time-resolved imaging of a selected region. High-resolution ECSTM has been applied to the anodic dissolution of pure metals, Cu,<sup>18–20</sup> Ni,<sup>21,22</sup> Ag,<sup>23</sup> Co,<sup>24</sup> and Pd,<sup>25</sup> and alloys, CuAu.<sup>26</sup>

**Figure 3** illustrates the process of dissolution, proceeding layer-by-layer *via* a step-flow mechanism at moderate potentials (i.e., slow etching rate). It was observed in this case at atomic resolution for Cu(001) in HCl<sub>aq</sub> with a fast-scan ECSTM.<sup>20</sup> Preferential etching of the surface takes place at the defects

**Figure 3** (a) Sequence of fast-scan ECSTM images (0.1 s per image) recorded on Cu(001) in 0.01 M HCl<sub>aq</sub> at  $-0.17$  V/SCE showing dissolution of a Cu terrace starting at the outer terrace corner. The observed lattice is formed by adsorbed chlorine. The markedly different dissolution behavior at the active and stable steps whose initial position is marked by solid and dashed lines, respectively, is clearly visible. (b) Model of the (001) surface of a face-centered cubic metal (e.g., Cu) covered by an ordered  $c(2 \times 2)$  adlayer (e.g., Cl) showing different structure of steps and kinks along the [010] and [001] directions. R and S mark the reactive and stable Cu atoms at the outer kinks, respectively. Reproduced from Magnussen, O. M.; Zitzler, L.; Gleich, B.; Vogt, M. R.; Behm, R. J. *Electrochimica Acta* **2001**, 46, 3725–3733.

corresponding to preexisting step edges. Selective etching of atoms at these sites results from their lower coordination to nearest neighbor atoms.

The superstructure formed by strongly adsorbed ions in the double layer region influences the anisotropy of the etching. In the absence of strongly adsorbed anions, the etching process, at moderate overpotentials, stabilizes the step edges oriented along the close-packed directions of the crystal where the nearest neighbor coordination of the atoms is maximum, e.g., along the atomically smooth  $\langle 1-10 \rangle$  and  $\langle 10-10 \rangle$  directions for (111)-oriented fcc metals and (0001)-oriented hcp metals respectively. On Cu(001), a highly ordered  $\alpha(2 \times 2)$  adlayer (observed in Figure 3) is formed in  $\text{HCl}_{\text{aq}}$  solutions. It stabilizes the step edges along the close-packed directions of the superstructure corresponding to the  $\langle 100 \rangle$  substrate directions. Atomic-scale imaging shows that the dissolution proceeds at structurally well-defined kinks of the [100]- and [010]-oriented steps *via* removal of the primitive unit cells of the Cl adlayer. Another effect of the  $\alpha(2 \times 2)$  adlayer is an induced anisotropy of the dissolution process along the symmetrical  $\langle 100 \rangle$  directions of the step edges. This is also visible in Figure 3 where one orientation of the step edges dissolves more rapidly than the other. This results from the structural anisotropy of the  $\langle 100 \rangle$  step edges induced by the presence of the  $\alpha(2 \times 2)$  adlayer, as illustrated by the model shown in Figure 3. This has been tentatively explained by the coordination of the outmost Cu atom forming the dissolving kink to the adjacent Cl adsorbates.<sup>20</sup>

In the double layer potential range, equilibrium fluctuations of these step edges are observed, which result from local removal/redeposition processes. These fluctuations are also illustrated by the sequence of fast-scan images shown in Figure 3. At more anodic potentials, the dissolution process prevails and a net removal is observed; but re-deposition still occurs.

### 2.33.3.2.2 Growth and structure of passive films

In the area of passivation, high-resolution ECSTM measurements have also been obtained with well-prepared single-crystal surfaces, bringing new insight into the mechanisms of self-protection of metal and alloys against corrosion in aqueous solutions. Data on this topic are available for Cu,<sup>27–29</sup> Ni,<sup>21,22,30,31</sup> Ag,<sup>32</sup> Co,<sup>33</sup> Fe,<sup>34</sup> Cr,<sup>35</sup> Al,<sup>36</sup> and ferritic<sup>37</sup> and austenitic<sup>38</sup> stainless steels.

The structural modifications of the electrode occurring at the active/passive transition as well as in the

potential range preceding oxide formation are illustrated here for Cu(111) in aqueous sodium hydroxide solution.<sup>27–29</sup> Figure 4 illustrates the growth of the adsorbed hydroxide layer on Cu(111) at potentials below that at which copper oxide is formed. The sequence of images shown in Figure 4(a) was obtained after stepping anodically the potential to  $-0.6 \text{ V}_{\text{SHE}}$ , below the active/passive transition at  $\sim -0.2 \text{ V}_{\text{SHE}}$ . The atomically smooth terraces of the surface (marked M) become progressively covered by darker-appearing islands (marked ad) that grow laterally and coalesce to cover the terraces completely. The darker appearance of these ad-islands is a typical effect of adsorbed O species also observed at the solid-gas interface.<sup>5</sup> The adsorbed layer preferentially grows at the step edges, confirming the preferential reactivity of these defect sites of the surface. The terraces grow laterally due to displacement of the step edges, and monoatomic ad-islands are formed at the end of the growth process. These two features are indicative of the reconstruction of the topmost Cu plane induced by the adsorption of the OH groups. The reconstruction causes ejection of Cu atoms from the original metallic surface layer. These ejected atoms diffuse on the surface and aggregate at step edges, which cause the observed lateral displacement of the step edges. In the final stages of the adsorption process, when most of the surface is already covered by the adlayer, the ejected atoms have reduced mobility on the OH-covered terraces and aggregate to form the observed monoatomic ad-islands.

Figure 4(b) shows an atomically-resolved image and model of the ordered  $\text{OH}_{\text{ads}}/\text{Cu}(111)$  surface that confirm the reconstruction of the Cu(111) topmost atomic plane. A hexagonal lattice with a parameter of  $0.6 \pm 0.02 \text{ nm}$  is measured. The interatomic distance between the Cu atoms is  $\sim 0.3 \text{ nm}$ , which is larger than the interatomic spacing of  $0.256 \text{ nm}$  in Cu(111), and confirms the reconstruction of the topmost Cu plane into a plane of lower atomic density. A coverage of  $\sim 0.2 \text{ OH}$  per Cu(111) atom is deduced from the density of the  $\text{OH}_{\text{ads}}$ , in excellent agreement with the coverage of 0.19 obtained from the electrochemical charge transfer measurements. In addition, the STM data show that the  $\text{OH}_{\text{ads}}$  sit in the three-fold hollow sites of the reconstructed Cu plane on which they form a  $(2 \times 2)$  structure.

Figure 5 illustrates the influence of the potential on nucleation, growth, crystallization, and structure of the  $\text{Cu}_2\text{O}$  oxide film formed in the potential range of Cu(I) oxidation. At low oversaturation (Figure 5(a)), mono-layer thick islands poorly crystallized and partially

**Figure 4** (a) Sequence of ECSTM images (38 s per image) showing growth of an adlayer of OH groups on Cu(111) at  $-0.6 V_{\text{SHE}}$  in 0.1 M  $\text{NaOH}_{\text{aq}}$ . Adapted from Maurice, V.; Strehblow, H.-H.; Marcus, P. *Surface Science* **2000**, 458, 185–194. (b) ECSTM image and model of the ordered structure of adsorbed OH groups formed on Cu(111). The large and small cells mark the lattice of adsorbed OH and reconstructed copper, respectively. Adapted from Kunze, J.; Maurice, V.; Klein, L. H.; Strehblow, H.-H.; Marcus, P. *Electrochimica Acta* **2003**, 48, 1157–1167.

**Figure 5** ECSTM images showing the effect of the potential on the growth and structure of the Cu(I) oxide formed on Cu(111) in 0.1 M  $\text{NaOH}_{\text{aq}}$  at  $-0.25 V_{\text{SHE}}$  (a) and  $-0.20 V_{\text{SHE}}$  (b). In (a), noncrystalline oxide islands (ox.) separated by the adsorbed OH layer (ad) partially cover the substrate. In (b), a crystalline oxide layer fully covers the substrate. Its atomic lattice (shown in the inset) corresponds to  $\text{Cu}_2\text{O}(111)$ . Adapted from Kunze, J.; Maurice, V.; Klein, L. H.; Strehblow, H.-H.; Marcus, P. *Journal of Physical Chemistry B* **2001**, 105, 4263–4269, with permission from American Chemical Society.

covering the substrate, are formed after preferential nucleation at step edges. They are separated by islands of the ordered hydroxide adlayer. At higher

oversaturation (Figure 5(b)), a well crystallized multi-layer thick film is formed, and the step edges are not preferential sites of nucleation. The equivalent thickness of the oxide layer can be deduced from subsequent measurements of the charge transfer during cathodic reduction scans. It was  $\sim 0.5$  and 7 equivalent monolayers (ML) of  $\text{Cu}_2\text{O}(111)$  after growth at  $-0.25$  and  $-0.2 V_{\text{SHE}}$ , respectively. The observed lattice of the ordered oxide layer is hexagonal with a parameter of  $\sim 0.3$  nm, consistent with the Cu sublattice in the (111)-oriented cuprite. The oxide grows in parallel (or antiparallel) epitaxy ( $\text{Cu}_2\text{O}(111) [\bar{1}\bar{1}0]||\text{Cu}(111) [\bar{1}\bar{1}0]$  or  $[\bar{1}\bar{1}0]$ ).

The crystalline Cu(I) oxide layer has a nanostructured surface consisting of facets. The surface faceting results from a tilt of a few degrees of the orientation of the oxide lattice with respect to the Cu lattice. A possible origin of the tilt is the relaxation of the epitaxial stress at the metal–oxide interface resulting from the large mismatch between the two lattices. The height of the surface steps of the oxide layer corresponds to 1 ML of cuprite, indicating an identical chemical termination of the  $\text{Cu}_2\text{O}(111)$  oxide terraces. It is thought that the surface of

the oxide layer is hydroxylated in the aqueous solution and that the measured lattice corresponds to OH and/or OH<sup>-</sup> groups forming a (1 × 1) layer on the Cu<sup>+</sup> planes of the (111)-oriented cuprite layers.

### 2.33.3.3 Electrochemical Tunneling Spectroscopy

With the potential of the substrate fixed by the electrochemical process under study and that of the tip adjusted to minimize the electrochemical tip current and optimize the STM measurement, the tunnel voltage can no longer be adjusted in a wide range as in UHV conditions. Thus, spectroscopic  $I$ - $V_{\text{bias}}$  measurements (TS) are most often restricted to a few hundreds millivolts range in an ECSTM cell.<sup>12</sup> However, recent developments allowing *in situ* single-point spectroscopic measurements (ECTS) over a larger range of tunnel voltage of nearly 3 V have been applied to Fe in a borate buffer solution.<sup>13</sup> The developments are based on the use of noble metals for tips (PtIr) combined with improved performance in tip isolation using electrophoretic coating. Ultrafast voltage ramps (up to 20 V s<sup>-1</sup>) are applied to vary the tip potential ( $U_T$ ) at a fixed sample potential ( $U_S$ ) and at a tunneling distance defined by the initial set-point conditions. The tip current ( $I_T$ ) is measured during the  $U_T$  ramp with the feedback loop switched off.  $I_T$ - $U_T$  curves measured at distances beyond the tunneling gap (with the tip retracted) are subtracted from  $I_T$ - $U_T$  curves measured at predefined tunneling distances. This procedure is used to eliminate capacitive and faradaic contributions to the tip current.

Tunneling spectra obtained by scanning  $U_T$  between -800 and +1500 mV/SCC at five different  $U_S$  values corresponding to various oxidation states of the Fe electrode versus  $U_T$  are plotted in Figure 6. The lower panel shows the tunneling conductance  $dI_T/dU_T$ , proportional to the Fe electrode DOS. It is obtained by numerical differentiation of the curves in the upper panel. The upper panel shows linear spectra for iron polarized at -800 and -650 mV. This results from a high and nearly constant density of surface states (or high surface conductance) of the metallic Fe(0) electrode. At -400 mV, an hydrated Fe(II) layer, a few nanometers thick and with unknown electronic properties, formed on the electrode surface in the specific conditions used in this study. A double exponential behavior is measured revealing a region of low current due to a decrease of the DOS. At 500 mV, the oxide layer is oxidized to

**Figure 6** ECTS spectra of Fe polarized at  $U_S = -800$ ,  $-650$ ,  $-400$ ,  $+500$ , and  $+900$  mV in a borate buffer aqueous solution. The upper panel shows tip current vs. tip potential curves. Solid lines and gray bands show average curves and standard deviations, respectively. The lower panel shows the conductance curves. See text for details. Adapted from Díez-Pérez, I.; Güell, A. G.; Sanz, F.; Gorostiza, P. *Analytical Chemistry* **2006**, 78, 7325–7329, with permission from American Chemical Society.

Fe(III) with well-characterized n-type semiconductive properties. A band gap in the DOS increases the separation between the exponential current branches. Its width is consistent with values reported for passivated iron ( $E_g = 1.6$ – $1.9$  eV). The positive current branch results from hole injection from the tip to the valence band (VB). At 500 mV, it is maintained by the slight depletion of the Fe(III) oxide film (upper inset marked #). At 900 mV, the positive current branch becomes extinguished due to stronger depletion conditions and demonstrates low density of charge carriers (upper inset marked ##). Both at 500 and 900 mV, the negative current branches result from electron injection from the tip to the conduction band (CB) of the oxide.

This spectroscopic data demonstrates the capability of ECTS to obtain *in situ* the electronic structure of the solid/electrolyte interface and measure the availability of charge carriers at the electrode surface. Series of tunneling spectra can be acquired stepwise over a large range of polarization potential and used to plot so-called conductograms (map of the conductance (i.e., the charge exchange properties) of the electrode as a function of potential), to study modifications resulting from a variation of the pH of the electrolyte or from the presence of chlorides. Up to now, such tunneling spectra have only been obtained in single-point mode, without combined imaging of the surface.

### 2.33.4 Atomic Force Microscopy

In contrast with STM, AFM, invented in 1986,<sup>39</sup> does not require conductive samples and tips. It can measure and image local forces between a surface and a tip, including van der Waals, Born repulsion, electrostatic and magnetic forces, friction, and adhesion.<sup>40</sup> The following presentation is restricted to topographic data derived from measurement of local forces on a length scale of  $10^{-10}$  to  $10^{-8}$  m.

#### 2.33.4.1 Principle and Operation

AFM is based on the variation of the interactions between two atoms or molecules. At very short distances, the interaction is repulsive and dominated by the electrostatic repulsion felt by the electrons as the orbitals start to overlap. At larger distances, the interaction is attractive and dominated by the dipole-dipole interaction between molecules. These interactions vary as inverse power laws of the distance,  $1/d^{12}$  and  $1/d^6$  for repulsive and attractive interactions, respectively. Their sum defines the total intermolecular potential  $U$ .

In AFM, this is the force ( $(-\partial U/\partial d)$ ) that is measured. The tip is positioned at the end of a cantilever spring (Figure 7). The deflection,  $d_z$ , of the cantilever is measured by an optical setup consisting of a laser beam reflected from the back side of the cantilever and impinging on a partitioned photodiode. The force on the cantilever is simply  $-k \cdot d_z$ ,  $k$  being the cantilever's spring constant. As in STM, a piezoelectric setup allows precise control of the tip position relative to the surface. A feedback loop is used to adjust the tip-surface distance in order to maintain the deflection (force) of the cantilever at a set-point

**Figure 7** Schematic diagram of the atomic force microscope and typical force curve showing the force on the cantilever as the tip-sample distance is varied.

value chosen by the operator when scanning the  $X$  and  $Y$  axes. This is the 'constant force' mode of imaging in which the tip reproduces the topographic profile of the surface. The lateral spatial resolution of the instrument is  $\sim 0.1$  nm when the interaction can be spatially limited to the atomic asperities of the tip. The vertical resolution is  $\sim 0.02$  nm.

The AFM user can choose to operate the microscope at any point along the typical force curve obtained when varying tip-sample distance (Figure 7). Contact occurs at the inflection point of the approaching curve where the curvature (i.e., derivative) changes from attractive to repulsive. Contact increases after this point as the tip-sample distance decreases. Contact-mode imaging is at risk of a potentially destructive interaction that can damage tip and/or sample. In air, stray adhesive forces ( $10^{-7}$  to  $10^{-8}$  N), resulting mostly from the presence of a condensed layer of water or other contaminants forming a capillary bridge between tip and surface, and at the origin of the hysteresis in the force curve, interfere to decrease the spatial resolution of the imaging. In addition, the dragging motion of the tip on the surface involves lateral shear force that can

distort measurement severely and induce lateral motion and/or tearing of surface features. The adhesive force is drastically reduced ( $\leq 10^{-9}$  N) in liquid applications where the whole cantilever–tip/surface assembly is immersed in solution. However the energy dissipated ( $\leq 1$  eV) by local interaction remains of the order of the energy of chemical bonds, and imaging in these conditions remains potentially destructive.

In the resonant (or Tapping®) mode, the cantilever–tip assembly oscillates at or near its resonance frequency with an amplitude of several nanometers. The oscillating tip is then moved toward the surface until contact. During scanning, the vertically oscillating tip alternately contacts the surface for force measurement and lifts off for implementation of the  $X, Y$  scan. This avoids dragging of the tip across the surface. The tip–sample separation is adjusted *via* the feedback loop of the microscope to maintain a constant oscillation amplitude and force on the sample. This resonant mode inherently prevents the tip from sticking to the surface and causing damage during scanning.

The noncontact mode is obtained for tip–surface distances larger than the one where the curvature of the force curve in **Figure 7** changes from negative to positive. Unfortunately, the attractive van der Waals forces are substantially weaker than forces used in contact mode and force resolution is poor. The consequences are a poor spatial resolution and a problematic thermal drift. The noncontact mode is more appropriate for UHV operation where the sample and tip can be cleaned from contaminants and the thermal drift is much less problematic. True atomic resolution can then be achieved when the tip–sample attractive force is such that the interaction is limited to a single atom at the tip apex.

#### 2.33.4.2 Electrochemical Implementation and Limitations

In ECAFM (electrochemical atomic force microscopy) the cantilever–tip assembly does not constitute a fourth electrode through which the electrochemical currents could flow, interfering with the signal used to probe the surface. Immersing the cantilever tip assembly and surface in solution allows better control of the adhesive force in contact mode (see above). In resonant contact mode, the fluid medium tends to damp the normal resonance frequency of the cantilever, which complicates this mode of operation. The noncontact mode becomes impractical because the van der Waals forces are even smaller, which can be a substantial limitation (e.g., for biological applications).

The limitations of ECAFM regarding the correlation between local information and integrated macroscopic information, possible tip-shielding effects on the corrosion behavior, kinetics of mass transport and small volume of the electrochemical cell are the same as those described for ECSTM.

#### 2.33.4.3 Application to Corrosion Analysis at the Solid–Liquid Interface

The application of ECAFM to corrosion analysis is much more widespread than that of ECSTM. ECAFM is often preferred because of its easier setup and because the obtained topographic information is independent of the conductivity of corrosion products. Moreover, ECAFM is most often used at the (sub) micrometer scale, i.e., at a lower level of spatial resolution that does not require preparation of atomically smooth surfaces as for ECSTM studies. ECAFM or AFM is often combined with a variety of other techniques to analyze corrosion and optimize corrosion protection properties. Corrosion protection by inhibitors<sup>41</sup> and coatings,<sup>42</sup> atmospheric corrosion,<sup>43</sup> passivation,<sup>44</sup> passivity breakdown,<sup>45</sup> localized corrosion,<sup>46,47,48,49</sup> and stress corrosion cracking<sup>50</sup> have been studied. We present examples of application to localized corrosion at inclusions.

The lower spatial resolution of AFM is appropriate to study pitting corrosion at microstructural defects (inclusions, grain boundaries, interphase boundaries) of metallic materials. **Figure 8** shows two images of localized corrosion observed *in situ* at the inclusion–matrix interface on an Al–Si(7.7 wt%) alloy under anodic polarization close to breakdown potential in 10 mM NaCl<sub>aq</sub> + 50 mM KI<sub>aq</sub>. **Figure 8(a)** shows localized dissolution occurring at the boundary surrounding a round-shaped particle of  $\sim 1$   $\mu$ m, whereas **Figure 8(b)** shows localized dissolution occurring between two irregular shaped particles (1–2  $\mu$ m size), while the boundary region to the matrix remains intact. The different nature of the particles present in the alloy (predominantly AlFeSi and eutectic Si phases) was advanced to explain the different corrosion behaviors of these particle/matrix boundaries.<sup>49</sup> A commonly advanced explanation for the formation of trenches around inclusions in Al alloys is that the inclusions act as cathodic sites for reduction of oxygen, causing the formation of an alkaline environment in the immediate vicinity of each inclusion, confirmed by local pH measurements.<sup>46</sup> This local increase of pH promotes local dissolution of the Al matrix.

**Figure 8** (a,b) ECAFM images of an Al-7.7 wt% Si alloy under anodic polarization close to breakdown potential in 10 mM NaCl<sub>aq</sub> + 50 mM KI<sub>aq</sub>. Localized corrosion around (a) and in between (b) inclusions is observed. Reproduced from Davoodi, A.; Pan, J.; Leygraf, C.; Norgren, S. *Applied Surface Science* **2006**, 252, 5499–5503. (c) ECAFM image of SUS304 stainless steel treated at a current density of 5 mA cm<sup>-2</sup> for 1500 s in 0.6 M NaCl<sub>aq</sub>. A crust of corrosion product is observed above a pit. Reproduced from Zhang, Q.; Wang, R.; Kato, M.; Nakasa, K. *Scripta Materialia* **2005**, 52, 227–230.

On stainless steels, studies have focused on the initiation of pitting near or at sulfide and carbide inclusions. On 304 SS, *ex situ* AFM combined with scanning electrochemical microscopy (SECM) and EDX analysis has shown that certain inclusions (sulfides) concentrate chloride, by electromigration, under a sulfur crust as a result of their dissolution evidenced by AFM. It has been proposed that the high local current density (evidenced by SECM), the electromigration of chloride, and the sulfur crust (evidenced by EDX) generate an occluded extreme environment in which stainless steel depassivates.<sup>47</sup> **Figure 8(c)** shows a crust of corrosion product on a small pit observed *in situ* on SUS304 treated anodically in NaCl (3.5 wt%) to trigger localized corrosion.<sup>48</sup> A part of the crust was destroyed, possibly by the scanning probe, and the pit hole remained shallow indicating repassivation. This was explained by the decrease of the concentration of chloride and hydrogen ions in the pit due to the destruction of the crust and stirring of the solution in the initially occluded environment in the pit.

### 2.33.5 Conclusion

The principles, instrumentation, and electrochemical implementation of STM and AFM have been presented. Both methods can provide 3D imaging of surfaces in direct space during corrosion processes. ECSTM is better suited for high resolution studies at the (sub)nanometer scale but is restricted to conductive surfaces. Atomic scale studies require a high level of control to produce atomically smooth

surfaces. ECSTM can be combined with ECTS to characterize the electronic properties of surface layers *in situ*. ECAFM is well-suited for (sub)micrometer scale studies of surfaces irrespective of their conductivity. Selected examples of applications to corrosion analysis show that both methods can greatly contribute to corrosion analysis and an improved understanding and control of corrosion of metals and alloys.

### 2.32.1 Introduction

Understanding the corrosion and protection of materials often requires examination of the morphology,

composition and structure of the surface and near-surface regions of a material, as well as their relationship to the bulk material. The knowledge gained allows definition of features that may increase susceptibility to degradation, and hence, routes for their removal.

Electron- and photon-based, spatially resolved techniques are widely used in corrosion studies. The selection of a technique for corrosion studies requires consideration of various factors, including:

- sensitivity/detection limit,
- elemental range,
- spatial resolution,
- depth penetration,
- quantitative/qualitative information,
- sample preparation,
- destructive/nondestructive procedure, and
- cost.

Usually, a single technique will provide only a part of the required information. For example, common approaches for morphological characterization include

- visual observation,
- optical microscopy (resolution  $\sim 1\ \mu\text{m}$ ),
- scanning electron microscopy (SEM) (resolution  $\sim 1\text{--}2\ \text{nm}$ ), and
- transmission electron microscopy (TEM) (resolution  $\sim 0.1\ \text{nm}$ ).

Typically, a combination of the techniques provides the comprehensive information required for the corrosion studies. **Figure 1** displays a set of optical, SEM and TEM images and an energy dispersive X-ray (EDX) spectrum obtained from a friction-stir-welded AA7108 aluminum alloy following corrosion testing for 72 h. The images reveal the propagation path of intergranular corrosion and the associated sensitized microstructure.

**Figures 1(a) and 1(b)** show the optical micrographs of the weld surface after corrosion testing. Semicircular marks created by the tool shoulder on the weld surface, evident at the center of the weld, are revealed as a series of ridges in the cross-section of the weld. Severe localized attack is evident in the heat-affected zone (HAZ),

**Figure 1** Corroded AA7108 aluminum alloy weld: (a) and (b) optical images; (c) scanning electron micrograph; (d) and (e) transmission electron micrograph; and (f) EDX spectrum taken from corrosion front.

where some ridges at the surface have been completely removed, with the attack extending through the HAZ to a depth of about 300  $\mu\text{m}$  from the original surface. However, the corrosion path is not resolved in the optical images. A scanning electron micrograph of the framed region in **Figure 1(b)** displays intergranular corrosion within the HAZ (**Figure 1(c)**). The dark lines in this backscattered electron image represent areas associated with relatively light elements compared with those of the adjacent regions. In this case, the dark lines represent corroded areas as corrosion products (i.e., aluminum oxide/hydroxide) contain oxygen and hydrogen, which are lighter than aluminum.

**Figure 1(d)** shows a transmission electron micrograph of an ultramicrotomed section taken from the corrosion front located in the framed region in **Figure 1(c)**. Significant attack of the region between the grains is evident, with the alloy bulk now being penetrated by the resin used to embed the specimen. Further, corrosion of the individual grains has resulted in the development of hydrated alumina of thickness about 90 nm; EDX analysis of the corrosion products gives the yields of aluminum and oxygen as expected (**Figure 1(f)**).

**Figure 1(e)** displays a transmission electron micrograph of an electropolished foil taken from the HAZ. At the grain boundary, distinct  $\text{MgZn}_2$  particles, about 100 nm length and 20 nm width, are evident, indicating sensitization of the HAZ that has led to the intergranular attack due to microgalvanic action.

### 2.32.2 Optical Microscopy

Optical microscopy is still a major tool in corrosion studies, being relatively cheap, readily available, and easy to use. Specimens can be observed in air. The images are of natural appearance, that is, color, with available resolution up to 1  $\mu\text{m}$  (**Figures 1(a) and 1(b)**). Optical microscopy is generally a reflection technique. A visible light beam is focused onto the area of interest. Reflected light beams pass through a single lens, or multiple lenses, to produce a magnified view of the examined area. The resultant image is detected directly by the eye, recorded on photographic film or captured by digital devices.

However, optical microscopes are limited in their ability to resolve fine detail by a phenomenon called diffraction. The resolution ( $\delta$ ) of an optical microscope is given by

$$\delta = \frac{0.5\lambda}{\text{NA}} \text{ NA} = \mu \sin \alpha \quad [1]$$

where NA or  $A_N$  is the numerical aperture of the optical microscope. Thus, the resolution is controlled by three factors:

- $\mu$  – the refractive index of the medium between the lens and the specimen;
- $\lambda$  – the wavelength of illuminating radiation;
- $\alpha$  – the half angle subtended by the maximum cone of rays entering the objective lens.

The resolution can be improved by increasing  $\mu$ ; for example,  $\mu$  can be increased from 1 to 2 by oil immersion. However, decreasing  $\lambda$  has the greatest potential to improve resolution. Visible light has wavelengths of 400–700 nm; with air as the medium, the highest practical NA is 0.95. Thus, the highest achievable resolution is  $\sim 0.2\text{--}0.4 \mu\text{m}$ .

In addition to the limitation on resolution, the depth of field is also relatively poor in optical microscopy. The depth of field is the portion of the object that can be seen acceptably sharply. The depth of field decreases as the magnification increases. Typically, the depth of field is 250  $\mu\text{m}$  at a magnification of  $15\times$  compared with 0.08  $\mu\text{m}$  at the magnification of  $1200\times$ .

In an optical micrograph taken at a relatively high magnification, only a section of the radiolarian is in sharp focus. Thus, flat specimens are required for optical microscopy. Therefore, metallography is employed to prepare a flat surface. Generally, metallic specimens that are to be examined in an optical microscope are mechanically polished to a 1- $\mu\text{m}$  finish. Examination in the as-polished condition reveals structural features such as porosity, cracks, and inclusion of foreign matter. Etching with appropriate chemical agents may be used to reveal the microstructural features such as grain size and phase distribution as grain boundaries are preferentially attacked by the etchants. **Figure 2** displays an optical micrograph of an AZ91D magnesium alloy after etching in a mixed etching solution (5 ml acetic acid, 10 ml water, 6 g picric acid, and 100 ml ethanol). The typical  $\alpha$  and  $\beta$  phases are clearly revealed.

A further limitation of conventional optical microscopy is that only dark or strongly reflecting objects can be imaged effectively. This limitation has, to some extent, been overcome by specific microscopy techniques using differences in the refractive indices of objects. To improve image contrast in optical microscopy, dark field or oblique illumination may be employed, but with no improvement in resolution. Other approaches include phase contrast microscopy, interference microscopy, and polarized light microscopy.

**Figure 2** Optical micrograph of AZ91D magnesium alloy after etching in a mixed solution (5 ml acetic acid, 10 ml water, 6 g picric acid, and 100 ml ethanol).

## 2.32.3 Electron Microscopy

### 2.32.3.1 Introduction

The limitations of optical microscopy are, to an extent, overcome in electron microscopy. From eqn [1], it is evident that the resolution is determined by the wavelength ( $\lambda$ ) of the radiation and the NA of the objective. To overcome the limitations set by the diffraction limit of visible light, electron microscopes that use electrons in place of light have been developed. This gives much increased resolution because the wavelength of the electrons is shorter, and hence, the diffraction limit is lower. At an accelerating voltage of 100 kV,  $\lambda$  is 0.0037 nm, giving the potential for significantly increased resolution in an electron microscope. Theoretically, a resolution of 0.02 nm is achievable in an electron microscope operated at 100 kV. Practically, however, such resolution cannot be obtained because of lens aberrations. The resolution limit presently is around 0.05 nm.

Further, the depth of field is also improved by using electrons for imaging. It is not unusual that the macroscopic specimen surface is in focus in a scanning electron microscope (SEM) because of the relevant large depth of field. However, as electrons can be readily scattered or absorbed in air, vacuum is required for electron microscopy, which makes the system more expensive with the need for effective maintenance.

Typically, an electron microscope consists of two components: the illumination system and the imaging system. The illumination system comprises the electron gun and the lenses that transfer the electrons from the gun to the specimen. Electrons are thermally

**Figure 3** Schematic diagram illustrating the generation of electrons and X-rays by a bulk specimen.

**Figure 4** Schematic diagram illustrating the interaction between the incident beam and the thin foil.

generated from a tungsten or lanthanum hexaboride ( $\text{LaB}_6$ ) cathode and are accelerated towards an anode. Alternatively, electrons can be emitted by field emission (FE). The latter produces an electron beam of fine size, increased brightness, and well-defined energies. The smaller energy spread of the FE gun, typically less than 0.5 eV compared with 1–2 eV for a thermionic source (e.g., tungsten or lanthanum hexaboride filament), is particularly important for electron energy loss spectroscopy (EELS).

In an electron microscope, incident electrons enter the specimen, interact with the material, and result in various secondary emissions, as illustrated in Figures 3–5. Each of the emissions may provide useful and different information about the material. Most of these emissions are used for imaging and analysis in the electron microscopy. Thus, electron microscopes generally require a source of incident electrons and a detector to collect the emitted

**Figure 5** Schematic diagram illustrating the regions where electrons and X-rays are generated.

radiation; often several detectors are combined in one system using a common incident electron beam.

When an electron beam is projected onto a specimen, various interactions between the incident electrons and the atoms of the specimen occur, including (i) elastic scattering, (ii) inelastic scattering, and (iii) combinations of (i) and (ii). Elastic scattering, which is the main contributor to the electron diffraction patterns, is due to the Coulombic interaction between the incident electrons and the atoms of the specimen, resulting in a change of direction, but not the energy, of the incident electrons. Inelastic scattering leads to energy transfer from the incident electrons to the electrons or atoms of the specimen. A small proportion of the lost energy may escape from the specimen as secondary electrons or X-rays, which are very useful for imaging and compositional analysis. Further, the detection of energy losses of the incident electrons is the basis of EELS.

As illustrated in **Figures 3 and 4**, in scanning electron microscopes, the images are generally generated by secondary and backscattered electrons, and in transmission electron microscope, the images are produced by the transmitted electrons. Determined by the image generation mechanism, SEM is used for studying the surface and near-surface regions of bulk specimens, and TEM is employed to investigate the internal structure of thin foil specimens.

The electrons lose energy by inelastic scattering within a region that is termed the interaction volume, which has a typical onion shape and extends approximately up to a few micrometres into the examined

material, as shown in **Figure 5**. The size of the interaction volume depends on the electron beam accelerating voltage, the atomic number of the elements in the specimen, and the material density.

### 2.32.3.2 Scanning Electron Microscopy

The application of SEM in corrosion studies is widespread, including (i) determination of structure–property relationships; (ii) location of corrosion; (iii) study of surface topography; (iv) examination of fracture sections and cracks; (v) and determination of the morphology of oxides, scales, corrosion products, etc.

In a typical SEM, a finely focused electron beam, of diameter down to 1 nm, is scanned across the surface of the specimen of interest. The scanning of the focused electron beam is achieved by controlling the current to the associated scan coils. The accelerating voltage in an SEM is typically in the range of a few hundred electron volts to 30 keV.

**Figure 3** illustrates schematically the electrons and X-rays generated through the interaction of an electron beam with the examined material. Although all resultant radiations can be used to produce an image, for SEM the images of surfaces are formed by collecting the low-energy secondary electrons (SEs) and backscattered electrons (BSEs). SEs are electrons that are ejected from atoms which interacted with the incident electrons and to which a small amount of energy has been transferred by the incident electrons during inelastic scattering; consequently, SEs have relatively low energies, below 50 eV, and escape only from regions up to 50 nm depth below the surface. The yield of secondary electrons is heavily influenced by the nature of the surface. BSEs are incident electrons that are backscattered from the specimen interaction volume. BSEs carry relatively high energies and, therefore, emerge from deeper regions within specimens. BSEs are used for imaging and generation of diffraction patterns for structure and texture analyses. These electrons may be used to provide compositional information by detecting the contrast between areas with different chemical compositions, especially when the average atomic number of elements in various areas is different, since the yield of BSEs varies with the atomic number of the elements in the examined specimen. Further, as illustrated in **Figure 3**, the relatively high-energy BSEs, emerging from deeper regions in the specimen, have an increased sampling volume; thus, generally, the surface sensitivity and resolution

**Figure 6** Corresponding secondary electron and backscattered electron images of a laser-surface-treated AA2024 aluminum alloy following accelerated corrosion testing.

**Figure 7** Backscattered electron images taken from (a) the parent alloy and (b) the HAZ of friction-stir-welded AA6082 aluminum alloy.

of the BSE approach are lower compared to that of the SE approach.

**Figure 6** shows the corresponding SE and BSE electron images of the surface of a laser-treated AA2024 aluminum alloy following accelerated corrosion testing. The SE image reveals clearly the typical wavy appearance generated by laser treatment, but with little evidence of development of corrosion. The contrast in the BSE image readily shows localized corrosion. The relatively dark areas represent the areas where corrosion has occurred, since corrosion products (i.e., mainly aluminum oxides/hydroxides in this case) consist of relatively light elements of oxygen and hydrogen compared to metallic aluminum, thereby generating a relatively low intensity of BSEs.

**Figures 7–9** display further BSE images taken from various specimens. **Figure 7** shows the BSE images from the parent alloy and the HAZ of a friction-stir-welded AA6082 aluminum alloy, revealing

the difference in the distribution, size and population density of intermetallics caused by thermal exposure during the welding process. Within the HAZ, a continuous network of  $\beta$  phase ( $\text{Mg}_2\text{Si}$ ) is clearly evident along grain boundaries, indicating sensitization of the HAZ. Such information assists in the understanding of the reasons for the HAZ of the friction-stir-welded AA6082 aluminum alloy displaying a relatively high susceptibility to intergranular corrosion.

The backscattered electron image of **Figure 8** displays the cross section of an AZ91D magnesium alloy after immersion in 3.5% NaCl for 4 h. As stated previously, the dark regions in this backscattered electron image represent areas of relatively light elements. In this case, the dark regions indicate corrosion products (i.e., magnesium oxides/hydroxides). It is clearly evident that corrosion occurred nonuniformly, with the areas of the  $\alpha$  phase being preferentially attacked and the  $\beta$  phase remaining generally intact.

**Figure 9** illustrates the backscattered electron images of a friction-stir-welded AA2024-T3 aluminum alloy following the immersion in an EXCO solution (ASTM G 34-01, a standard testing method for exfoliation susceptibility in 2xxx and 7xxx series aluminum alloys) for 8 h. Again, the dark regions in these BSE images represent corroded areas. At the surface, a severely corroded band is evident. On the right side of the corrosion band (**Figure 9(a)**), that is, in the parent alloy, little development of corrosion is observed. Conversely, on the left side of the corrosion band, that is, within the thermomechanically affected zone (TMAZ), a large number of randomly distributed pits, of dimension about 50–300  $\mu\text{m}$ , is evident. Further, the weld cross-section revealed clearly that localized corrosion has penetrated into the alloy from both top and bottom surfaces.

A topographic image may be obtained using SEM. **Figure 10(a)** displays an SE image of an oxide film formed on a binary Al–Cu alloy, revealing the different topographies of the oxide film formed on three individual alloy grains of different crystallographic

**Figure 8** Backscattered electron image of the cross section of AZ91D magnesium alloy after immersion testing in 3.5% NaCl solution for 4 h.

**Figure 9** Backscattered electron images of friction-stir-welded AA2024-T3 aluminum alloy following corrosion testing in the EXCO solution for 8 h, revealing corrosion susceptible zones where the alloy was sensitized during welding: (a) plan view and (b) cross sectional view of (a).

orientations. Since the shape and size of the SE sampling volume is related to the angle between the surface and the incident electron beam, as the angle increases, the escape distance of one side of the beam will decrease and, consequently, more SEs will be emitted. Thus, steep surfaces and edges tend to be brighter than flat surfaces, resulting in images with a well-defined topographic contrast. It is essential to tilt the specimen to obtain the desirable topographic contrast, avoiding signals emitted from deeper regions within the specimen, and thereby enhancing the surface sensitivity in topographic studies. For example, **Figure 10(b)** was obtained from the framed area in **Figure 10(a)** without tilting the specimen, revealing little topographic contrast although features of subsurface regions of the specimen (i.e., voids in the oxide film in this case) are clearly displayed. This is because the surface topographic contrast is overwhelmed by internal features since a relatively large portion of signal is emitted from deeper regions

within the specimen. **Figure 10(c)** illustrates schematically the cross section of the oxide film, revealing the distribution of the voids. It is clearly evident that the internal features of the oxide film overwhelmed the surface topographic features.

#### 2.32.3.2.1 Electron backscatter diffraction

Electron backscatter diffraction (EBSD), also known as backscattered Kikuchi diffraction (BKD), allows crystallographic information to be obtained from any crystalline material using BSEs in the scanning electron microscope. EBSD can be used to determine grain sizes and shapes, as well as orientations and misorientations. Such information is very useful for corrosion studies. For example, the sensitization of an alloy may be correlated to misorientations between alloy grains. Because of the relatively weak channeling contrast used for EBSD, a carefully prepared surface is essential to obtain satisfactory information. Normally, a flat and strain-free surface is desirable.

**Figure 10** (a) and (b) Scanning electron micrographs of an oxide film formed on an Al-Cu binary alloy; and (c) schematic illustration of the cross section of the oxide film.

Such a surface may be produced by electropolishing. Mechanical polishing should be avoided in EBSD specimen preparation since a near-surface layer of deformed microstructure is normally introduced into the materials during the process. **Figure 11** displays the EBSD maps recorded in various weld zones of a friction-stir-welded AA2024 aluminum alloy, revealing grain size and orientations. The parent alloy and the HAZ were shown to consist of a relatively coarse, elongated grain structure, ranging from approximately  $20 \times 30 \mu\text{m}$  to  $50 \times 150 \mu\text{m}$  in dimensions that were generated during fabrication. The nugget region, that is, the center of thermomechanically affected zone (TMAZ), displays relatively small, equiaxed grains of size about  $1\text{--}10 \mu\text{m}$ . Outside the nugget, within the TMAZ, a heavily deformed parent microstructure is revealed.

### 2.32.3.2.2 Environmental scanning electron microscopy

Environmental scanning electron microscopy (ESEM), developed in the 1980s, allows operation in increased pressure gaseous environments, in the range of 1–10 torr,

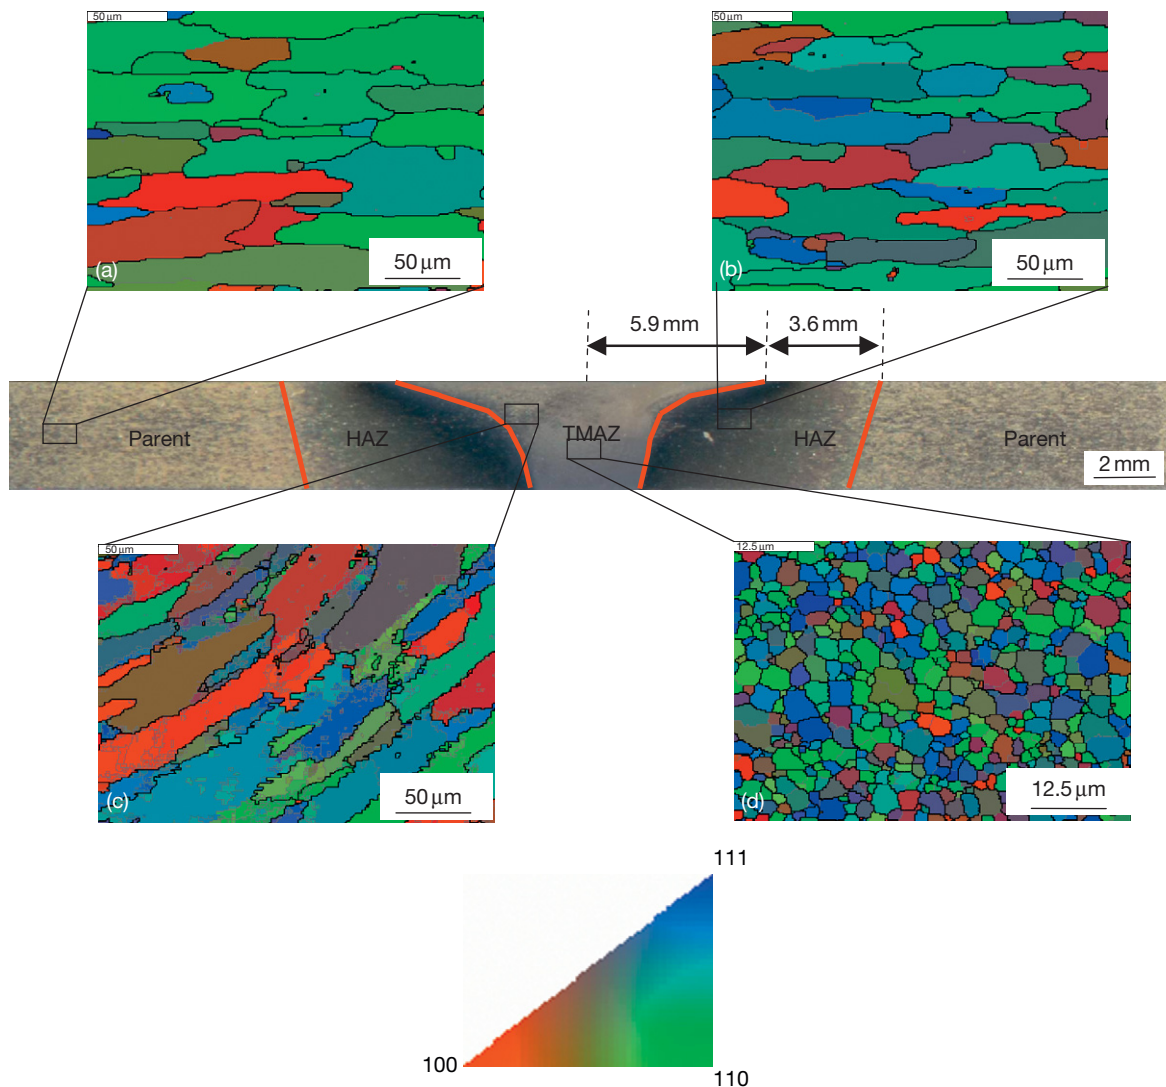

compared to a vacuum below  $10^{-5}$  torr in a conventional SEM. This is achieved by the development of an SE detector that is capable of operating in the presence of gases and by the use of electron apertures and differential pumping systems to separate the high-vacuum regions around the gun and the column from the low-vacuum sample chamber. Therefore, in corrosion studies, ESEM allows imaging of specimens with a vapor or volatile component, or while *in situ* examinations involve gas or liquid phases. Additionally, ESEM allows examination of nonconductive specimens without coating since the excess electrons are dissipated by the collision between the electrons and gas molecules.

### 2.32.3.3 Transmission Electron Microscopy

The application of TEM in corrosion studies includes (i) structure–property relationships determination; (ii) sites of corrosion and surface roughness determination, (iii) morphological determination of oxides, scales, corrosion products, etc.

TEM forms images following the transmission of an electron beam through an electron-transparent specimen. An image is formed, magnified, and directed to appear either on a fluorescent screen or photographic film, or detected by a sensor such as a CCD (charge-coupled device) camera. In a typical TEM, electrons are generated from a tungsten or lanthanum hexaboride ( $\text{LaB}_6$ ) filament or a FE gun which accelerates electrons through voltages in the range 40–300 kV. Over the years, high-voltage (up to 3 MV) TEMs have been developed to achieve improved resolution and increased penetration, but they have become rarer since the resolution of relatively low-voltage TEMs being improved through improved lens design, and thin specimen preparation techniques being developed. Further, FE guns are now becoming increasingly widespread because of the capability of producing electron beams of very fine diameter (0.2 nm), increased brightness, and well-defined energies. In a TEM, a parallel or convergent beam can be generated. The former is used for imaging and diffraction, and the latter is used for scanning transmission electron microscopy (STEM), microanalysis, and convergent beam electron diffraction (CBED).

As illustrated in **Figure 4**, when an electron beam is projected onto a thin foil specimen, various processes occur, including (i) the straight passage of electrons through the specimen, (ii) elastic scattering, (iii) inelastic scattering, and (iv) combinations of (ii) and (iii). The intensity of the transmitted beam is affected

**Figure 11** Electron backscatter diffraction (EBSD) maps recorded in various weld regions of friction-stir-welded AA2024 alloy: (a) the parent alloy; (b) the HAZ; (c) the TMAZ; and (d) the nugget region.

by the volume and density of the material through which the beam passes. The thick regions, or regions of increased density, scatter electrons strongly and appear dark in the image. This gives a mass-thickness contrast. However, a crystalline material can also interact with the electron beam by diffraction. The intensity of the diffraction depends on the orientation of the planes of atoms in a crystal relative to the incident electron beam. This is known as diffraction contrast.

In TEM, an objective aperture is placed at the focal plane of the objective lens to select electrons to form the image. The objective aperture can then be used to allow either the unscattered beam or the diffracted beam to form images. If the objective aperture is

centered at the optical axis, the electrons that are deflected away from the optical axis are blocked, and only unscattered electrons pass through to form an image. This is known as a bright field (BF) image since in the absence of a specimen a bright background is seen on the screen. It is also possible to produce an image from electrons that are deflected by particular crystal planes. By either moving the objective aperture to the position to block the unscattered electrons and allow a particular diffracted beam to pass through, or tilting the incident electron beam so that a particular diffracted beam passes through the centered aperture, an image can be formed by the deflected electrons. This is known as a dark field (DF) image

since in the absence of a specimen the background appears dark. BF and DF images provide valuable complementary microstructural information.

**Figure 12** shows a pair of BF and DF images of an ultramicrotomed section of an AA6111 aluminum alloy that was solution-heat-treated (SHT) at 813 K for 30 min followed by rapid quenching in ice water before mechanical grinding with 220 grit SiC paper and heat treatment at 180 °C for 30 min. The mechanical grinding introduced a deformed layer microstructure, which is characterized by very fine grains, approximately 50–150 nm diameter. Further, the DF image (**Figure 12(b)**), achieved by choosing the electrons deflected by a particular set of planes in the precipitate to form the image, reveals precipitate particles of approximately 20 nm diameter distributed along grain boundaries.

Using an annular detector to collect electrons that have been inelastically scattered through relatively

**Figure 12** Transmission electron micrographs of ultramicrotomed section of the AA6111 alloy: (a) bright field image and (b) dark field image.

large angles, compositional information of the specimen may be obtained by acquiring a Z-contrast image since the inelastic scattering is proportional to the square of the atomic number  $Z$ . Thus, areas with higher average atomic number elements appear brighter and areas with lower average atomic number elements appear darker. For example, etching or anodizing of copper-containing aluminum alloys normally results in the formation of a thin layer of alloy, about 2 nm thick, immediately beneath the residual or anodic alumina film, which is highly enriched in copper. Such enrichment arises from the less negative Gibbs free energy per equivalent for formation of copper oxide compared to alloys. **Figure 13(a)** shows a high angle annular dark field (HAADF) image of a cross-section of an AA6111 aluminum alloy after anodizing, revealing the Z contrast from the copper-rich band located at the alumina–aluminum interface. However, such a copper-rich band appears as a dark band in the BF image (**Figure 13(b)**) because of the mass contrast, that is, enhanced electron scattering by copper compared to aluminum.

A further example of the use of TEM in corrosion studies is given in **Figure 14**. A scanning electron micrograph of a cross-section taken from an AA6111 aluminum alloy is shown in **Figure 14(a)**, revealing localized corrosion which has proceeded into the alloy to a depth of  $\sim 4 \mu\text{m}$ . However, the SEM image provides little information about the corrosion initiation sites and propagation paths. **Figure 14(b)** displays the transmission electron micrograph of an ultramicrotomed section taken from the region indicated with the frame in **Figure 14(a)**. It is now clearly revealed that the corrosion is intergranular and develops preferentially along grain boundaries.

However, TEM requires consideration of the means of preparation of electron-transparent specimen. Thus, many materials require extensive specimen

**Figure 13** Transmission electron micrographs of cross-sections of AA6111 aluminum alloy after (a) anodizing and (b) caustic etching.

**Figure 14** (a) Scanning electron micrograph of cross-section of corroded AA6111 aluminum alloy and (b) transmission electron micrograph of an ultramicrotomed section taken from corrosion front as indicated by the frame in (a).

preparation to produce a specimen sufficiently thin to be transparent to electrons. Often, the specimen preparation is a time-consuming process with low throughput. Further, the composition and structure of the material may be changed during specimen preparation processes. Additionally, the sampling volume in TEM is relatively small, raising the possibility that the region examined may not be characteristic of the bulk material.

As stated previously, inelastic scattering generates useful signals. However, there is also the potential that the specimen may be damaged by the high-energy electron beam during inelastic scattering. Electron beam damage changes the structure and chemistry of the examined materials. Certain materials are more susceptible to damage than others. Inelastic scattering may break the chemical bonds of materials such as polymers. Further, the kinetic energy that is carried by the incident electrons may be transferred to heat in the specimen during the inelastic scattering processes. Electron-beam heating of thermally conductive materials such as metals is negligible under standard condition but can be quite

**Figure 15** Transmission electron micrographs of an ultramicrotomed section of the anodic film formed to 200 V on the Al-2 wt% Cu alloy: (a) upon immediate examination in electron microscope, revealing a featureless amorphous film attached to the substrate and (b) after continued exposure to the electron beam in the microscope, the inner film region showing crystallization of alumina.

substantial if thermal conduction is poor. For example, in [Figure 15](#), a transmission electron micrograph of an ultramicrotomed section of the anodic film formed on the Al-2 wt% Cu alloy reveals a featureless amorphous film attached to the substrate. With continued exposure to the electron beam, the inner region of the anodic oxide film is crystallized to  $\gamma'/\gamma$  alumina, as shown in [Figure 15\(b\)](#). However, such changes are not always problematic and advantage may be taken from such changes. From [Figure 15\(b\)](#), it is evident that the thickness of the crystalline region adjacent to the alloy substrate is about 60% of the total film thickness; the outer region, representing about 40% of the total film thickness, showed delayed crystallization. This suggests that about 40% of the total film thickness is formed at the film–electrolyte interface by cation migration, and the remainder formed at the aluminum–film interface by anion migration since the outer region of the film contains incorporated, immobile electrolyte species that retard crystallization of the contaminated amorphous alumina under electron irradiation.

### 2.32.3.3.1 High-resolution TEM

High-resolution TEM (HRTEM) allows the imaging of the crystallographic structure of materials at an atomic scale. The image formation in HRTEM relies on phase contrast. As mentioned in [Section 2.32.1](#), theoretically, a resolution of 0.02 nm is achievable in an electron microscope. However, such resolution cannot be obtained because of lens aberrations. At present, the highest resolution achieved is 0.05 nm on HRTEM with aberration correctors.

**Figure 16** HRTEM image of a Q-phase particle in AA6111 aluminum alloy.

**Figure 16** shows an HRTEM lattice image of a grain boundary precipitate in AA6111 aluminum alloy. The particle extends through the thickness of the section, with no consequent interference from the surrounding aluminum matrix. The lattice fringe spacing was determined accurately by using the (111) lattice plane spacing of the aluminum matrix as a reference. The measured fringe spacing of the precipitate is 0.898 nm, in good agreement with the  $d$  value of 0.899 nm for the  $\{100\}_Q$  set of planes, thereby confirming that the precipitate is the quaternary Q phase ( $\text{Cu}_2\text{Mg}_8\text{Si}_7\text{Al}_4$ ). The revelation of the Q phase at the grain boundary helps in explaining the occurrence of intergranular corrosion of the same alloy, as revealed in **Figure 14**. Where the Q-phase particles are formed at grain boundaries, the microgalvanic coupling between the particles and the adjacent matrix to the particles provides the driving force for localized corrosion.

Further, although the high-angle annular dark field and BF image of **Figure 13** revealed that a copper-enriched layer of 2 nm thickness formed at the aluminum–oxide interface by anodizing and caustic etching of the AA6111 aluminum alloy, it is impossible to tell how the copper species exist in the band from **Figure 13**. Such information can be readily obtained by using HRTEM. **Figure 17** displays a lattice image of the copper-enriched layer, revealing clearly the lattice fringe spacing and confirming the presence of a  $\text{CuAl}_2$  particle within the copper-enriched layer.

**Figure 17** (a) Transmission electron micrograph of cross-section of AA6111 aluminum alloy after caustic etching, revealing a copper-rich band at the aluminum–oxide film interface; and (b) HRTEM lattice image of a  $\text{CuAl}_2$  particle in the copper-rich band.

### 2.32.3.3.2 Scanning transmission electron microscopy

Scanning transmission electron microscopy (STEM) is a combination of SEM and TEM: that is, a transmission image is obtained using a scanning method. A TEM can be modified into an STEM by the addition of a system that scans a focused beam across the specimen to form the image. Further, by fitting a transmission stage and a detector, an SEM can also be operated in the STEM mode. Thus, a STEM combines some of the advantages of the SEM and the TEM. The image obtained in an STEM is similar to that obtained in a TEM, but the data are acquired serially.

In recent years, dedicated STEMs have also been built. In a dedicated STEM, since no objective or projector lenses are needed after the specimen, a relatively large space is available for various signal detectors to be positioned in. Thus, the dedicated STEM is normally used as a multisignal analytical microscope with high spatial resolution. Since the resolution of an STEM is determined by the diameter of the focused electron beam, the beam is focused to as small a size as possible. Nowadays, in a dedicated STEM, using a FE electron gun, an electron beam of diameter 0.2 nm can be generated. This is sufficient to image heavy single atoms. The employment of dedicated STEMs is limited since they are comparatively expensive and the improvement in the electron beam size in TEMs equipped with a FE gun has significantly reduced the difference in the resolution of the two types of microscope.

### 2.32.3.3.3 TEM tomography

Typically, TEM microscopy generates two-dimensional (2-D) images which locate the position of an internal feature in the examined specimen both vertically

and horizontally but with no information on the depth of that feature within the specimen being obtained. However, information concerning the depth of the feature can be obtained by tilting the specimen in small steps (small angle) and acquiring a series of 2-D images at each angle and subsequently reconstructing 3-D images by merging the individual 2-D images into a single 3-D block that can then locate any feature in the specimen in any direction. This technique is termed TEM tomography.

#### 2.32.3.3.4 Electron diffraction

Electron diffraction is a technique that allows determination of the crystal structure of materials. When the electron beam is projected onto a specimen, its crystal lattice acts as a diffraction grating, scattering the electrons in a predictable manner, and resulting in a diffraction pattern. Electron diffraction patterns are mainly contributed by elastic scattering. In an electron microscope, the diffraction pattern appears either on a fluorescent screen or is recorded on a photographic film or detected by a sensor such as a CCD (charge-coupled device) camera. From the diffraction pattern, the arrangement of the atoms in a material can be determined. Electron diffraction can be acquired with either TEM or SEM (electron back-scattered diffraction).

Selected area diffraction (SAD) is often employed to obtain a diffraction pattern from the area of interest, such as one grain in a polycrystalline specimen or a second phase embedded in the matrix. SAD is achieved by either inserting an aperture in the plane of the specimen itself or the first image produced by the objective lens, or illuminating only the area of interest. By using a convergent electron beam, diffraction patterns can also be obtained from fine regions. This technique is called convergent beam electron diffraction (CBED).

There are many reasons for obtaining diffraction patterns in corrosion studies. For example, by obtaining diffraction patterns, an unknown material may be identified, or the relationship between the grain orientations and the surface properties of a material may be established. **Figure 18** displays diffraction patterns obtained from (a) a single crystal of tin along the  $[001]_{Sn}$  zone axis, revealing a regular array of sharp spots since several sets of planes that are approximately parallel to the incident electron beam diffract electrons, thereby giving rise to a diffraction pattern; (b) a fine-grained polycrystalline AA 6111 aluminum alloy, exhibiting a ring-like diffraction pattern since the

**Figure 18** Electron diffraction patterns: (a) a single crystal of tin along the  $[001]_{Sn}$  zone axis, (b) a fine-grained polycrystalline AA6111 aluminum alloy, and (c) amorphous carbon.

diffraction pattern is the sum of individual crystals of random orientations and (c) amorphous carbon, showing amorphous diffusion rings.

### 2.32.4 Chemical Analysis in the Electron Microscope

Chemical analysis in the electron microscope provides spatially resolved compositional information which is not available in conventional chemical or spectrographic methods.

### 2.32.4.1 X-ray Analysis

As stated previously, in an electron microscope, the energy lost by the incident electrons during inelastic scattering may escape from the specimen as X-rays. If an inner-shell electron has been knocked out of an atom during the inelastic scattering of an incident electron by that atom, the atom is in an excited high-energy state. The vacancy will be filled by an electron from an outer higher energy shell and the atom will relax. The excess energy of that electron is released in the form of an X-ray or an Auger electron. The X-rays are highly specific to individual elements, known as characteristic X-rays. For example, if a K shell electron has been removed from an iron atom and the vacancy is filled by an L shell electron, the energy difference,  $\Delta E$ , is 6400 eV. The corresponding wavelength of the emitted X-ray can be calculated from  $\lambda = hc/\Delta E$  to be 0.193 nm. The energy (wavelength) can be measured to determine the composition of the examined material since the energy (wavelength) is characteristic to a particular element. Thus, the emitted X-rays can be processed by two different approaches: using an energy dispersive spectrometer (EDS) or a wavelength dispersive spectrometer (WDS). Further, X-ray analysis is non-destructive and may be quantitative.

In an EDS, semiconducting silicon or germanium is used as the X-ray detector. The detector converts each absorbed X-ray photon into an electrical current pulse that is proportional to the energy of the X-ray photon. Each current pulse is amplified by a computerized analyzer. A histogram of energies of all X-rays arriving at the detector is collected and displayed as a smooth curve, which is the EDS spectrum. Normally, a window is necessary to separate the detector from the specimen chamber to prevent condensation on the detector since the detector works at very low temperatures. Unfortunately, such windows can absorb a significant portion of low-energy X-rays, thereby making light elements particularly difficult to be detected. However, windowless detectors or detectors with ultrathin windows are available to detect elements down to boron in the periodic table.

The main drawbacks of EDS systems are the relatively poor energy resolution, typically within the range of 100–200 eV, and a low signal-to-noise ratio, which make it difficult to resolve characteristic X-rays with sufficiently close energies and affect the detection, and therefore its use for quantitative analysis. The minimum detection limit for any element is about 0.1% using an EDS system and an order of

magnitude lower using a WDS system. As an EDS detector can be placed very close to the specimen, thereby collecting X-rays very efficiently, a spectrum for qualitative analysis can be acquired within a couple of minutes.

In WDS, the arriving X-rays are filtered by a crystal spectrometer using diffraction to separate the X-rays on the basis of their wavelength. Then, X-rays of the energy resolution and signal-to-noise ratio are achieved, making it possible to resolve characteristic X-rays of close energies and to undertake more accurate quantitative analysis. Thus, the main drawbacks of EDS are overcome in a WDS system. However, since only one wavelength is detected at a time, it is very time consuming to acquire a spectrum.

Further, a characteristic X-ray is most efficiently generated when the primary electrons carry approximately 3 times the energy of the X-ray. Therefore, by using a SEM operating at 30 keV all elements are readily detectable since they have at least one strong characteristic X-ray line with energy less than 10 keV. In SEM, the surface sensitivity of X-ray analysis is related to the accelerating voltage since the penetration of the primary electrons is dependent on the beam energy: that is, accelerating voltage. With reducing accelerating voltage, electrons have less energy and hence penetrate to shallower depths; thus, X-rays are generated from regions close to the specimen surface.

Although secondary emission is generated throughout the entire interaction volume, which extends approximately a few micrometers into the examined materials, only that escaping from the specimen is detected. Most X-rays generated can escape from the specimen since X-rays are not readily absorbed. Thus, in the SEM, the X-rays are generated from a relatively large volume of material, of typical dimensions 2–3  $\mu\text{m}$ . As illustrated in [Figure 3](#), the sampling volume of X-rays is similar to the interaction volume, but the sampling volume of SEs and BSEs are significantly smaller. A large portion of X-ray signals are contributed by materials that are not seen in SE or BSE images. Thus, in SEM, an unseen phase below the surface may be detected during X-ray analysis, as illustrated in [Figure 19](#).

Therefore, the spatial resolution of X-ray analysis in SEM or electron probe microanalysis is limited to the sampling volume of the X-rays, which is typically at the level of micrometers although the imaging resolution of SEMs can achieve 1 nm. It is difficult to reduce the sampling volume below  $\sim 1 \mu\text{m}^3$  without reducing the energy of the incident electron

**Figure 19** Schematic diagram illustrating the sampling volumes of imaging and X-ray analysis in SEM.

beam to the degree that no useful X-rays are generated. However, as illustrated in [Figure 5](#), the lateral spread of the interaction volume and X-ray sampling volume increases with the depth of penetration. Thus, the problem can be overcome by using a sufficiently thin specimen in the TEM. With the use of such a specimen in the TEM, the X-ray sampling volume is approximately equivalent to the imaging region. Thus, the spatial resolution of X-ray analysis in the TEM is approximately the probe size, typically of diameter down to  $\sim 1$  nm. However, the small amount of X-rays generated by the low current of such a small probe from a small sampling volume of the thin specimen makes meaningful analysis difficult. Practically, it is difficult to achieve meaningful analysis with a probe size of diameter much less than 10 nm for a typical specimen.

Further, in a TEM, the specimen is closely surrounded by the specimen holder and supporting grid, which can interfere with the analysis since X-rays can also be generated by BSEs from the specimen holder and the supporting grid. Such interference can be minimized by using a beryllium specimen holder which generates X-rays that are not detectable and by using grids made of a material that is irrelevant to the specimen. It is also critical to ensure that the grid is placed in a direction such that the specimen faces the incident beam, thereby minimizing interference.

If only one spot or area is analyzed, quantification of the relative proportions of elements under that spot or area is possible, which is known as point analysis ([Figures 1](#) and [20](#)). If a line of pixels is analyzed, changes in the proportions of elements with distance along the line can be determined, which is termed X-ray line scanning. Each pixel in an image can also be analyzed, illustrating the locations and amounts of a selected element across the image, which is known as X-ray mapping.

**Figure 20** (a) Transmission electron micrograph of the cross section of the interface between the adhesive and the anodic porous alumina film formed on aluminum substrate and (b) EDX spectra taken from the areas indicated in (a).

[Figure 20\(a\)](#) illustrates the TEM image of the cross section taken from the interface region of adhesively bonded aluminum that was pretreated by chromic acid anodizing (CAA). The morphology of the porous anodic film formed by CAA is readily revealed from observation of the cross-section displayed in [Figure 20\(a\)](#). The anodic film is well wetted by the adhesive, and the relatively open morphology of the outer region of the anodic film allows significant penetration of the adhesive. However, the extent of penetration of the adhesive into the pores of the anodic film cannot be determined precisely from the micrograph. Hence, energy dispersive analysis of X-rays was performed by placing an electron probe at various locations across the section of the anodic film/adhesive interface. [Figure 20\(b\)](#) shows the EDX spectra. Spectrum A, taken from the aluminum substrate, indicates that only aluminum is detected. Spectra B, C and D were taken within the

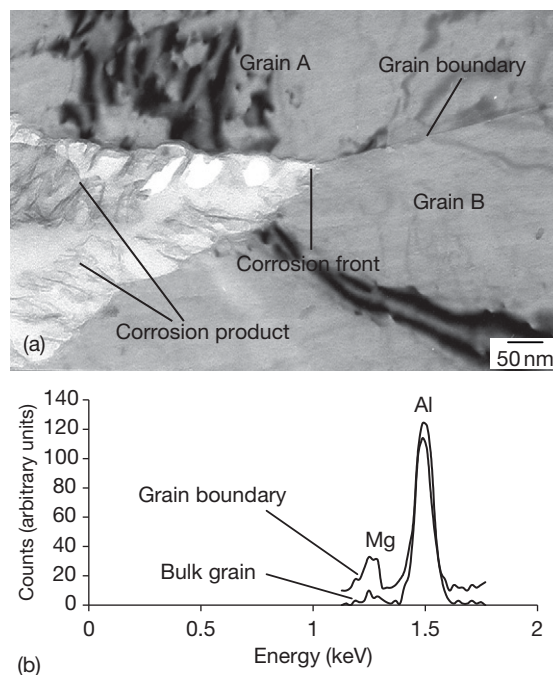

anodic film close to the interface with the aluminum substrate and in the middle and the outer region of section of the anodic film, respectively, indicated the presence of Al, O and, additionally, C and Si; C and Si arise from the adhesive (spectrum (E) taken from the bulk adhesive) that had penetrated into the film. This suggests that the adhesive penetrated significantly into the porous anodic film.

**Figure 21(a)** shows a transmission electron micrograph of an ultramicrotomed section of an AA5182 aluminum alloy after accelerated corrosion testing, revealing the corrosion front and the intact grain boundaries ahead of the corrosion front. Significant attack along a grain boundary is evident. **Figure 21(b)** shows the EDX spectra generated from a probe located at the grain boundary and within the bulk grains. For an electron probe of a nominal diameter 20 nm located on the boundary, an increased yield of magnesium was detected compared with that from the bulk grain, suggesting the presence of a magnesium-rich phase at the grain boundary since the relative peak height (area) is generally proportional to the concentration of individual elements in the specimen. The revelation of the magnesium-rich phase, probably  $\beta$  phase ( $\text{Mg}_2\text{Al}_3$ ), at the grain boundary helps in explaining the occurrence of intergranular attack of the alloy. Since the magnesium-rich phase is anodic with respect to bulk grain, when such phases are formed at grain boundaries, the microgalvanic coupling between the magnesium-rich phase and the adjacent grain matrix provides the driving force for localized corrosion.

**Figure 22** illustrates the line scan profiles across a precipitate revealed in the DF image of the AA6111 aluminum alloy shown in **Figure 12**. By scanning with an electron probe of nominal diameter  $\sim 2$  nm across the precipitate and the adjacent grain matrix, changes in the proportions of elements with distance along the line are determined. Increased yields of copper, magnesium and silicon at the grain boundary particles are detected with respect to the grain matrix, suggesting the presence of the Q phase ( $\text{Cu}_2\text{Mg}_8\text{Si}_7\text{Al}_4$ ). Notably, no solute-depleted zones are readily detected in the vicinity of the grain boundary precipitates or at the grain boundary itself.

#### 2.32.4.2 Electron Probe Microanalysis

Electron probe microanalysis (EPMA) is a nondestructive technique that allows determination of the composition of small volumes of a solid material. In an electron probe microanalyzer, an electron beam is

**Figure 21** (a) Transmission electron micrograph of ultramicrotomed section of AA5182 aluminum alloy after accelerated corrosion testing, revealing the corrosion front and (b) EDX spectra taken from the intact grain boundary and bulk grain.

**Figure 22** EDX line scanning profiles across a precipitate revealed in **Figure 12** of the dark field image of AA6111 aluminum alloy.

generated and directed to a specimen to be examined and a wavelength dispersive spectrometer is employed to detect the X-rays emitted from the specimen. By scanning the electron beam and fitting an electron detector, complementary images may also be obtained. In this mode, an EPMA is similar to the SEM. As stated

previously, WDS provides much improved energy resolution and signal-to-noise ratio compared to EDS. However, to achieve more accurate quantitative analysis and to cover the full X-ray spectrum, a range of crystals of different lattice spaces is required. Further, the mechanics of WDS place strict geometric restrictions on the positions of the specimen, crystal spectrometer, and the detector. These make it difficult, but not impossible, to fit such a system into an electron microscope. Thus, a purpose-built electron probe microanalyzer is necessary. Typically, four computer-controlled crystal spectrometers containing a range of crystals of different lattice spacing are installed in a dedicated EPMA system. Such equipment can achieve more accurate quantitative analysis than X-ray analyses in a standard electron microscope. EPMA can quantitatively analyze elements down to boron in the periodic table at levels as low as 100 ppm.

Mapping of elemental distributions by EPMA in the cross-section of a coating formed on an aluminum substrate anodized for 1800 s at  $5 \text{ A dm}^{-2}$  in 0.05 M potassium hydroxide/0.15 M sodium metasilicate electrolyte is shown in **Figure 23**. Oxygen is revealed in all regions of the coating thickness, apart from cavities. Other elements are less uniformly distributed. Notably, aluminum is largely absent in some regions of size up to  $50 \mu\text{m}$ , which are enriched in silicon. These regions were found at various depths within the coating, including regions close to the metal.

#### 2.32.4.3 Electron Energy Loss Spectroscopy

As discussed previously, a primary electron that undergoes any inelastic interaction with the examined material loses energy. EELS determines the losses of electron energy. The most commonly used EELS is transmission EELS, in which the energy loss of incident electrons with a known, narrow range of kinetic energy passing through a thin specimen is determined by an electron spectrometer that is mounted after the specimen in the TEM.

Typically, an EELS spectrum consists of three regions: (i) zero loss peak, resulting from electrons that have suffered negligible inelastic scattering; (ii) low loss region, containing electrons that have suffered inelastic scatterings including phonon excitations, inter- and intraband transitions, plasmon excitations, and have lost up to  $\sim 50 \text{ eV}$  energy and (iii) high loss region, containing electrons that have suffered interaction with tightly bound inner shell electrons and caused inner shell ionization, which is characteristic of the element. Although each region of

the EELS spectrum provides complementary information, it is the characteristic edges in the high energy loss region that are most commonly used. In TEM, EELS is capable of obtaining spatially resolved information on composition, chemical bonding as well as valence and conduction band electronic structure since the spectra for an element in different compounds are different. This ability is a strong advantage of EELS compared with EDX.

A further advantage of EELS compared to EDX is its capability of detecting light elements that generate X-rays that are too soft to be detected, such as helium, lithium, and beryllium. The probability that a particular electron will be scattered by an atom is defined as the cross-section, which decreases for elements of high atomic number. Thus, light element edges are far more intensive than those of elements with higher atomic number. Thus, EELS is very powerful for the analysis of light elements.

In corrosion studies, spatially resolved EELS has been successfully applied, for example, to the study of local chemistry of anodic oxide films. A correlation between flaws in the oxide film and changes in the oxygen gas generation has been established via spatially resolved EELS. **Figure 24** shows a transmission electron micrograph of ultramicrotomed section of the anodic film formed at a constant current density of  $50 \text{ A m}^{-2}$  on a binary Al-4 at.% Cr alloy in 0.01 M ammonium pentaborate solution to 32 V, revealing an anodic film of  $\sim 40 \text{ nm}$  thickness. Variation of film morphology is clearly evident. Light regions of different sizes are revealed within the film section. **Figure 25** displays the EELS spectra at the oxygen K-shell electron ionization energy region acquired from locations across the film from the film surface to the alloy/film interface; the separation of the spectrum line is  $0.8 \text{ nm}$ . The spatially resolved oxygen K-edge fine structure encompassing a region of light film materials reveals a sharp pre-edge peak at  $529 \text{ eV}$  before the OK edge; such pre-edge peaks are characteristic of oxygen gas. Thus, it is concluded that the light regions in the film are bubbles filled with oxygen gas.

Further, the valence state of chromium species that have been incorporated into the film from the substrate alloy has also been determined by EELS. Using the data generated from anodic alumina,  $\text{Cr}_2\text{O}_3$  and  $\text{K}_2\text{Cr}_2\text{O}_7$ , spectra have been simulated for anodic alumina with associated  $\text{Cr}^{3+}$  or  $\text{Cr}^{6+}$  species. From the simulation and measurement of the experimental spectrum acquired at a location in the anodic film, as shown in **Figure 26**, it is evident

**Figure 23** EPMA of the cross section of aluminum anodized for 1800 s at  $5 \text{ A dm}^{-2}$  in  $0.05 \text{ M}$  potassium hydroxide/ $0.15 \text{ M}$  sodium metasilicate electrolyte at  $293 \text{ K}$ : (a) scanning electron micrograph, (b) aluminum map, (c) oxygen map, (d) potassium map, (e) sodium map, and (f) silicon map.

**Figure 24** Transmission electron micrograph of an ultramicrotomed section of the anodic film formed at a constant current density of  $50 \text{ A m}^{-2}$  on a binary Al-4 at.% Cr alloy in 0.01 M ammonium pentaborate solution to 32 V.

**Figure 25** EELS spectra acquired at a series of locations from close to the film surface to the alloy-film interface for the film displayed in [Figure 24](#).

that  $\text{Cr}^{3+}$  species was incorporated into the anodic film during the anodization of Al-4 at.% Cr alloy.

If EELS spectra are acquired from each pixel in an image, the distribution of a chosen element at certain oxidation state across the image can be analyzed, which is known as EELS mapping. For example, the DF image of [Figure 12\(b\)](#) reveals precipitate particles of  $\sim 20 \text{ nm}$  diameter distributed along grain boundaries in the examined AA6111 aluminum alloy. However, no compositional information is revealed in [Figure 12\(b\)](#). Such information can be readily obtained by EELS mapping. [Figure 27](#) shows EELS maps of precipitates in the AA6111 aluminum alloy revealed in [Figure 12\(b\)](#). The bright areas represent relatively high intensities of signals. Mapping images of  $508 \times 508$  pixels were acquired, giving a pixel size of  $0.92 \times 0.92 \text{ nm}$  for the selected magnification. The images were selected at the Al K, Cu  $L_{2,3}$ , Mg K and Si K edges, with onsets at 1560, 931, 1305 and 1839 eV, respectively, and energy resolution of about 0.6 eV. The EELS maps of [Figure 27](#) confirm

**Figure 26** Simulated and experimental EELS spectra: (a) simulated spectrum for anodic alumina containing  $\text{Cr}^{3+}$  species, (b) simulated spectrum for anodic alumina containing  $\text{Cr}^{6+}$  species, (c) experimental spectrum acquired at a location in the anodic film close to the alloy-film interface.

**Figure 27** EELS maps showing the distribution of precipitates in AA6111 aluminum alloy. The bright areas represent relatively high intensity of signals.

that the fine particles contain increased levels of copper, magnesium and silicon compared to the matrix. Examination of the images also reveals regions in which only silicon was detected, as shown by arrows, indicating the presence of two different types of precipitates in the alloy.

Comparing [Figure 27](#) with the X-ray maps (EPMA or EDX, [Figure 23](#)), it is clearly evident that EELS mapping has significantly improved the spatial resolution. This is because the spatial resolution of X-ray analysis in SEM or electron probe

microanalysis is limited to the sampling volume of the X-rays, which is typically at the level of micrometers although the imaging resolution of the SEMs is as high as 1 nm.

### 2.32.5 Specimen Preparation Techniques

Successful electron microscopy is essentially dependent on the employment of appropriate specimen preparation techniques that can produce revealing specimens and avoid, or minimize, change to the materials.

#### 2.32.5.1 TEM Specimen Preparation

Since TEM forms images following transmission of an electron beam through the specimen, thin foil specimen of thickness from a few nanometers to a few hundred nanometers must be prepared. For example, at an accelerating voltage of 100 kV, the maximum thickness of a transparent specimen is about 100 nm depending on the density of the material. The task is made even harder by the need to precisely prepare thin foil specimens from interesting regions within a large sample. Thus, preparation of TEM specimen can be a very challenging and time-consuming operation. The commonly employed TEM specimen preparation techniques include

- electropolishing,
- chemical polishing,
- ion beam thinning,
- deposition,
- film stripping,
- ultramicrotomy, and
- replication.

Depending on the type of materials being studied, appropriate preparation techniques should be chosen to generate an electron-transparent specimen.

TEM specimens from materials that have dimensions sufficiently small to be transparent to an electron, such as powders or nanotubes, can be quickly produced by the deposition of a suspension containing the material onto support grids. The suspension is normally made by diluting the sample in a volatile solvent such as ethanol. The solvent rapidly evaporates after depositing the suspension onto support grids, thereby producing a specimen that is suitable for TEM. Dry powder may also be directly dusted onto support grids.

The surface of a solid sample cannot be observed in TEM directly. The examination of a surface of a solid sample is achieved by replication. The replication process typically involves molding the surface of interest in a thin replica material which is transparent to electrons and subsequently removing the replica from the surface. Then the replica, which has copied the features on the surface, is ready for examination in the TEM.

Thin oxide films can be stripped from metal substrates by a chemical stripping process and transferred to supporting grids for TEM examination. Electropolishing is the most commonly employed technique for preparing thin foil specimen from electrically conductive materials such as metals. Chemical polishing is frequently used for generating TEM specimens from nonconductive materials such as semiconductors and ceramics. The main drawback of both electropolishing and chemical polishing is that a certain component of the material may be preferentially leached to change the specimen, thereby leading to inaccuracies in the subsequent TEM characterization.

Ion beam thinning is widely used to prepare an electron-transparent foil from hard materials including metals and ceramics. Focused ion beam (FIB) thinning is a relatively new technique that can be employed to prepare thin foils from precisely selected regions in a relatively large sample of any material. However, the highly energetic ion beam may introduce artifacts such as amorphization of the materials or contamination to the resultant thin foil specimen. Such artifacts introduce noticeable effects when lattice images are examined in HRTEM or EELS analysis is carried out.

In corrosion studies, ultramicrotomy is a very powerful tool. With experience, very revealing specimens can be produced. The principal advantages of ultramicrotomy are that it can create uniform thin foils and maintain the integrity of a multiphase sample ([Figure 20\(a\)](#)), for example, enabling thin foil specimens to be generated displaying the interface between the metal and its protective coatings ([Figure 13](#)) or exhibiting corrosion sites with corrosion products being kept in its original location ([Figures 1, 14, and 21](#)). However, ultramicrotomy may introduce mechanical damage, mainly compression, to the thin foil specimen; also reaction may occur between the materials and water in the bath behind the diamond knife employed in ultramicrotomy. The latter can be used to advantage in corrosion studies in the case of employing thin foil specimen to investigate the relationship between the microstructure and corrosion initiation.

**Figure 28** Transmission electron micrographs of an ultramicrotomed section of an aluminum alloy before/after immersion in water.

**Figure 28** shows transmission electron micrographs of the ultramicrotomed section of an aluminum alloy before and after the immersion in water;  $\alpha$ -FeSiAl-particle-induced localized corrosion of the alloy matrix, due to the cathodic nature of the particle with respect to surrounding matrix, is revealed.

### 2.32.5.2 SEM Specimen Preparation

Compared to TEM, SEM allows much larger specimens to be examined, and specimen preparation is much simpler. Examination of bulk specimens makes it possible to image a comparatively large area. In corrosion studies, it is often needed to examine the cross-section of a specimen to determine corrosion propagation paths, the extent of corrosion beneath the surface, the thickness of a protective coating and its morphology in inner regions, its composition profile and adhesion to substrate, etc. In addition to conventional methods, such as mechanical polishing, for the preparation of the cross-section, new methods such as ultramicrotomy are increasingly employed to produce cross-section specimens with significantly reduced roughness, mechanical damage and contamination, thereby producing revealing specimens for the new generation of SEMs that provides very high surface sensitivity by avoiding interference between signals from different depths of specimens.

Further, with the typical operation voltages (20–30 kV), the number of electrons that escape from the specimen is smaller than that of electrons that hit the specimen. Consequently, there is a

buildup of electrons at the specimen surface if the excess electrons are not conducted away from the specimen, leading to the specimen surface becoming negatively charged. As a result, the incident electrons are repelled, and the image is distorted. Thus, for a nonconductive specimen surface, such as a metal with corrosion products or oxides films on the surface, the surface must be coated with a thin conducting layer, such as carbon or gold–palladium, which does not readily form an insulating oxide layer in air during its transport from the coating unit to the microscope. Thus, the build-up of electrons at the specimen surface is avoided by conducting the excess electrons away from the specimen by the conducting coating. However, there are drawbacks for the employment of such coatings. The coatings may mask fine surface features. The coating may also absorb some of the X-rays emitted from the specimen during X-ray analysis. The absorption is more pronounced by coating with elements of higher atomic number such as gold/palladium. An alternative approach to the surface charging problem is to operate the SEM at a relatively low voltage (1–5 kV) so that excessive electron build-up at the specimen surface is minimized.

### 2.32.6 Other Techniques

#### 2.32.6.1 X-ray Microscopy

##### 2.32.6.1.1 Introduction

X-ray microscopy is a nondestructive technique that generates an image of the internal features of the

examined materials, with the image contrast being determined by the difference in absorption of X-rays by the different components in the materials. The first X-ray microscope was developed in the late 1940s. In the X-ray microscope, images are recorded on photographic film or detected by a sensor such as a CCD camera. Similar to visible light, X-rays are a form of electromagnetic energy, but with much shorter wavelength and much higher energy. The resolution of X-ray microscopy lies between that of light microscopy and electron microscopy since an X-ray microscope uses soft X-rays with a wavelength in the range of 10 to 0.01 nm. Resolutions of nanometer level are achievable using the Fresnel zone plate lens which forms the image using the soft X-rays emitted from a synchrotron or from a laser-produced plasma. Further, because of their high energy, X-ray microscopes have the ability to penetrate relatively deep into materials, allowing images to be generated from the internal features. Compared to TEM, X-ray microscopy can generate images from relatively thick samples. A further advantage over electron microscopy is that X-ray microscopy does not require particular specimen preparation or a high-vacuum sample chamber.

#### 2.32.6.1.2 X-ray tomography

Standard X-ray microscopy can generate 2-D images which locate the position of an internal feature in the examined specimen both vertically and horizontally but with no information on the depth of that feature within the specimen being obtained. However, the information concerning the depth of the feature can be obtained by X-ray tomography. X-ray tomography is a 3-D scanning technique that allows nondestructive, high-definition scans of a specimen to be made. 3-D tomography requires the collection of a series of 2-D X-ray images on all sides of the specimen. Subsequently, highly detailed 3-D images are reconstructed by merging the individual 2-D X-ray images into a single 3-D block which can then locate any feature in the specimen in any direction. Systems with zone plate lenses can provide spatial resolution better than 50 nm.

The ability of nondestructive imaging of the internal features of materials in three dimensions gives X-ray tomography critical advantages in applications such as failure analysis as well as fundamental research. For example, internal cracks can be observed in three dimensions and correlated to the microstructure of a material; intergranular corrosion may be examined and correlated to grain boundary compositions; the

**Figure 29** X-ray tomography image of isotropic nuclear graphite, revealing porosity introduced by the fabrication process. Courtesy D. James, A. Jone, T.J. Marrow, and N. Stevens, Materials Performance Centre, School of Materials, The University of Manchester.

3-D approach can also lead to an improved understanding of interfacial reactions that occur at the intermetallics–matrix interface during pitting. This may lead to significant insight and understanding of the relationship between the microstructure and performance, that is, susceptibility to corrosion. X-ray tomography may also be extended to the observation of real-time processes of crack growth and corrosion propagation. **Figure 29** shows an image of isotropic nuclear graphite obtained on the Swiss Light Source TOMCAT synchrotron, revealing the porosity introduced by the fabrication process.

#### 2.32.6.2 Infrared Microscopy

Infrared spectroscopy is a technique based on the specific resonant frequencies of molecules, that is, the frequencies at which they rotate or vibrate. The resonant frequencies can be related to the strength of specific bonds and the mass of the atoms forming the bonds. Thus, the frequency of the vibrations can be associated with a particular bond type. When an infrared beam is directed to the material to be examined, the rotation or vibrations can lead to infrared absorptions at characteristic frequencies that are related to specific chemical groups in the material. The infrared spectrum is obtained by measuring the absorption at each wavelength. Thus, infrared spectroscopy can provide direct molecular identification of the examined materials.

In an infrared microscope, spatially resolved infrared spectra are obtained to form images, with the contrast being determined by the response of

individual specimen regions to particular wavelengths, generating a molecular fingerprint from the specimen. For infrared microscopy, as well as Raman microscopy, which is discussed in the next section, there are two approaches to acquire the spectrum. These approaches are known as parallel acquisition and serial acquisition. For parallel acquisition, the area of interest is fully illuminated by the incident beam; then, a micrograph is generated at a chosen wavelength which is characteristic of a molecular compound. For the serial mode, a finely focused incident beam is rastered across the surface of the materials to be examined, generating spatially resolved spectra. Subsequently, the micrograph is reconstructed to display the locations and amount of molecular compounds within the area of interest. Infrared microscopy employs focal plane array detection for infrared chemical imaging. The spatial resolution of infrared microscope is limited to about 10  $\mu\text{m}$  depending on the wavelength of light and the aperture. A typical infrared microscope operates over the range 650–4000  $\text{cm}^{-1}$ .

In corrosion studies, infrared microscopy can provide valuable information on interfacial reactions such as inhibition of metals and chemical bonding between a protective coating and the substrate. Further, by measuring at a specific frequency over time, changes in the character or quantity of a particular bond can be measured. This is especially useful in measuring the degree of polymerization in an organic protective coating. The infrared microscope operates in three different modes, transmission, reflection, and absorbance, depending on the transparency of the material to be examined. Materials that are transparent to infrared may be investigated in the transmission mode, which usually requires that the specimen is polished on both sides. For the reflectance mode, little specimen preparation is required.

### 2.32.6.3 Raman Microscopy

Like infrared spectroscopy, Raman spectroscopy is also based on the vibration or rotation of molecules within the material of interest. Thus, similar information is generated by Raman spectroscopy. However, infrared spectroscopy and Raman spectroscopy yield complementary information since they are based on different physical principles. Raman spectroscopy is based on inelastic scattering, or Raman scattering, of the incident monochromatic radiation by the material. Normally, a monochromatic source of light is used as the incident radiation. Highly

monochromatic and intense lasers in the visible, near-infrared or near-ultraviolet regions are usually employed as incident radiation in a modern Raman spectroscope. The interaction between the material and the laser beam results in phonons or other excitations, leading to the energy of the laser photons being shifted. Thereafter, the laser beam is collected with a lens and transferred through a monochromator. Wavelengths close to that of the incident radiation, due to elastic Rayleigh scattering, are filtered out, while the rest of the collected light is dispersed onto a detector to generate the spectrum. Thus, Raman spectroscopy allows the molecular identification of species present in the examined materials since the energy shift of the laser beam is associated with specific molecules in the materials.

A typical Raman microscope consists of a standard optical microscope, a laser, a monochromator, and a detector. A CCD or photomultiplier tube (PMT) is normally used as the detector. Relatively long acquisition times are required when a photomultiplier tube is used. The acquisition time is significantly reduced with CCD detectors. In Raman microscopy, the micrograph is obtained by generating spatially resolved spectra in the parallel or serial acquisition mode. The spectra are then analyzed and used to form a corresponding chemical image that shows the location and amount of different components within the examined area. Raman microscopy has relatively high spatial resolution. The lateral and depth resolutions are approximately 0.3 and 2  $\mu\text{m}$ , respectively. Raman microscopy cannot be performed on materials that exhibit fluorescence, since fluorescence yields a much more intense signal than Raman scattering and, therefore, masks any Raman bands that might be present. For incident radiation of wavelengths less than 785 nm, fluorescence interference can be very common. Moving to long-wavelength lasers can mitigate much of the fluorescence interference. However, the efficiency of Raman scattering decreases as the fourth power of wavelength, making long-wavelength Raman microscopes much less sensitive than systems based on visible wavelengths. Since Raman spectroscopy is a scattering technique, specimens do not need to be specially prepared.

Recently, Raman spectroscopy has been successfully combined with SEM and scanning probe microscopy (SPM), allowing morphological, compositional, structural and chemical analyses without moving the specimen between instruments. The features of interest are precisely located using the SEM and SPM and are chemically identified using Raman spectroscopy.

**Figure 30** Raman micrograph of chromate-inhibited primer: (a) optical image, (b)  $\text{TiO}_2$ , (c)  $\text{BaSO}_4$ , and (d)  $\text{SrCrO}_4$ . Courtesy Dr A.E. Hughes, CSIRO Manufactory and Infrastructure Technology, Australia.

**Figure 30** displays the Raman micrographs of a cross-section of the interface between an AA2024 aluminum alloy and chromate-inhibited epoxy polyamide primer, revealing the distribution of various components, including  $\text{TiO}_2$ ,  $\text{BaSO}_4$  and  $\text{SrCrO}_4$  in the primer. Raman micrographs were generated using peaks at  $866$ ,  $987$ , and  $638\text{ cm}^{-1}$  for  $\text{SrCrO}_4$ ,  $\text{BaSO}_4$  and  $\text{TiO}_2$ , respectively. It is clearly evident that  $\text{TiO}_2$  is distributed relatively uniformly throughout the primer, whereas  $\text{BaSO}_4$  and  $\text{SrCrO}_4$  exhibit locally high concentration corresponding to relatively large particles of these two phases in the primer.

### 2.32.7 Concluding Remarks

This chapter is written mainly on the basis of experiences in the Corrosion and Protection Centre at The University of Manchester. The authors acknowledge the many colleagues who have also contributed significantly to the application of electron- and photon-based spatially resolved techniques in corrosion studies.

Leading scientists around the world continue to raise expectation for electron microscopy, and the manufacturers of electron microscopes continue to meet the expectation with improved design of the electron microscope. The introduction of the FEI Titan TEM in 2005 is a good example. In the Titan microscope, aberration correction breaks through the fundamental optical limitations of magnetic lenses. The Titan's extra wide column was specifically designed to give the mechanical stability required by the added height of probe and image correctors.

Its proprietary constant power lenses and advanced power supplies provide the necessary thermal and electronic stability. Titan enables sub-Angstrom microscopy in both TEM and STEM modes. The Titan can also achieve energy resolution down to  $0.1\text{ eV}$  for EELS, obtaining information of the electronic properties of materials, such as bonding states or band gaps, with unprecedented spatial resolution. Titan ETEM extends the capabilities of conventional TEM by permitting gas in the specimen chamber (up to  $4\text{ kPa}$ ) along with specimen heating (up to  $1000^\circ\text{C}$ ), thereby allowing investigation of interactions between the material and the local gaseous environment.

Although this chapter is entitled 'electron- and photon-based spatially resolved techniques,' it would not be complete without mentioning the increasing sophistication in microscopy, for example, the recently developed Carl Zeiss ORION helium ion microscope. The scanning ion microscope uses a beam of helium ions as the incident radiation. Like a conventional SEM, in a scanning helium ion microscope the ion beam is rastered across the surface of the material to be examined. Since ion beam can be focused to a finer size, with less surface interaction than electrons, the scanning ion microscope can generate images with increased resolution and better contrast, more surface sensitivity, and better depth of field. Further, as in the case of Rutherford backscattering spectroscopy, backscattered helium ions can be collected in the helium ion microscope, with the total backscattered ion yield being directly proportional to the mass of the sample atoms. Thus, it is possible to easily differentiate between elements.

For those who wish to pursue the subject further, there are many textbooks that provide much more detailed information on electron- and photon-based spatially resolved techniques.

## 2.34.1 Introduction

Corrosion tests provide the basis for the practical control of corrosion and therefore deserve a more exhaustive discussion than limitations of space will permit. A detailed description of all the procedures and devices that have been employed in corrosion studies in many countries will not be attempted. Instead, attention will be directed principally to underlying principles and to comments on the significance and limitations of the results of the test methods that are considered. Further details may be obtained from the references and from the comprehensive works by Champion<sup>1</sup> and Ailor.<sup>2</sup> (See also: Baboian, R.; Dean, S. W. *Corrosion Testing and Evaluation: Silver Anniversary Volume*, ASTM STP1000-EB; ASTM: Philadelphia, 1990; 436 p. and Cramer, S. D.; Covino, B. S., Jr., Eds. *ASM Handbook Volume 13A: Corrosion: Fundamentals, Testing, and Protection*, ASM International, Ohio, 2003; 1135 p.)

Tests may be classified conveniently under three headings.

1. Laboratory tests, in which conditions can be precisely defined and controlled.
2. Field tests (tests in real environments), in which replicate test samples of metals or alloys – referred to as test coupons or specimens – are exposed to the actual environmental conditions expected in service, for example, the atmosphere, the ground, the sea, etc.
3. Service tests, in which the test specimens – which may often take the form of manufactured components – are exposed to the particular conditions in which they are to be used, for example, in process streams of chemical plant.

## Symbols

**$b_a, b_c$**  Tafel constants for anodic and cathodic processes

**$E$**  Potential

**$E_b$**  Pitting breakdown potential

**$E_{corr}$**  Corrosion potential

**$E_p$**  Pit repassivation potential

**$i$**  Current density

**$i_a, i_c$**  Net anodic and cathodic current densities

**$i_{corr}$**  Corrosion current density

**$i_L$**  Limiting current density

**$i_o$**  Exchange current density

**$I$**  Total current

**$Q$**  Electrical charge

Laboratory tests, although often necessarily conducted under conditions that are not met in service, have a number of advantages over the other types of tests. Since conditions can be controlled at will, it is possible to identify the separate effects of a number of factors on the corrosion behavior. These factors include the type and condition of the metal surface, the environmental composition, temperature and pressure, movement of the specimen relative to the environment, time of exposure, and so on. Laboratory tests, at least in principle, also enable comparisons to be made under identical conditions of the relative corrosion behavior of different metals and alloys and different protective schemes, for example, coatings, environmental treatments, etc.

In many cases, attempts will be made to accelerate the test to produce results in a shorter time than might otherwise be possible in field or service tests. Such acceleration is usually achieved by intensifying one or more of the controlling factors. Tests might be conducted at a higher temperature, with more corrosive media, with activation of the corrosion process by electrochemical methods, etc., with the object of enhancing the aggressivity of the test conditions. While accelerated test procedures are often used, the results should always be treated with careful consideration. It is not unknown for a protective system to fail to meet the requirements of an accelerated test, although showing satisfactory performance in normal conditions of use. Nevertheless, a number of such tests, particularly for atmospheric corrosion, in which rates of corrosion in real conditions are often low, are accepted and correlations have been established with real conditions. (Such tests are typically designed and standardized for very specific conditions, such as the performance of nickel–chromium-plated components for automotive applications, and care should be taken when applying them for other situations. A key requirement for any accelerated test is that it should produce the same type of corrosion (uniform, pitting, etc.) as in the service exposure.)

Field tests do not have the uncertainties attached to accelerated laboratory tests, since there is no attempt to adjust the controlling environmental conditions. The chief problem is obtaining reproducible conditions from one test to another. This is particularly the case with tests in the atmosphere. While broad classes of terrestrial atmospheres have long been recognized, for example, tropical, rural, urban, marine, etc., difficulties remain that are associated with variations within these classes. In the 1980s, steps were taken within ISO to rationalize the situation by producing a standard on the classification of atmospheres (ISO 9223). Other

standards that provide guidance on the mounting and disposition of specimens for field tests (ISO 8565) and for the statistical treatment of results where large numbers of specimens are used (see Ailor<sup>2</sup> and ASTM G 16) are available.

Service tests will be used: (1) where the operating conditions cannot be successfully reproduced in laboratory tests, (2) where the environment does not occur naturally, (3) where real components, as opposed to test specimens, need appraisal, and (4) to confirm laboratory and/or field tests.

Often, all the three types of test will be used sequentially. An example might be the development of a coating to protect suspension cables for use on a bridge in a coastal region. The test program could involve salt spray testing of candidate treatments in the laboratory, followed by field trials of the most successful materials at a site similar in aggressivity to the location of the final product and eventual testing at the site with loadings and positioning matching those of the end use. It would be expected that the number of candidate materials would decrease through this sequence of tests.

Irrespective of the method of test or the purpose for which it is made, there are certain practical features that require attention and will be necessary to achieve good reproducibility (by one operator) and repeatability (by different operators).

## **2.34.2 Test Procedures**

### **2.34.2.1 Preparation of Surface**

When the test is to predict the performance of a material in a particular service, the ideal procedure would be to have the surface of the test-pieces duplicate the surface of the material as it would be used. Here, however, a complication is presented by the fact that materials in service are commonly used in several forms with different conditions of surface. Where the number of materials to be compared is large, it will usually be impractical to test all the conditions of surface treatment of possible interest. The best practical procedure, then, is to choose some condition of surface more or less arbitrarily to allow the materials to perform near the upper limits of their ability. If all the materials to be tested are treated in this way, and preferably with uniform surface treatment, the results of the test will indicate the relative abilities of the different materials to resist the test environment when in a satisfactory condition of surface treatment. Then, if it should be considered prudent or desirable to do so, the most promising materials can be subjected to

further tests in a variety of surface conditions so that any surface sensitivity can be detected.

These remarks apply as well to the treatment of the surfaces of specimens to be used in tests in corrosion research projects, except that here, selection of a particular method of surface preparation is required to achieve reproducibility of results from test to test and among different investigators. Methods of preparing specimens are described in ASTM G 1 and ISO 7539-1.

The final step in surface preparation should ordinarily be a cleaning and degreasing treatment to remove any dirt, oil, or grease that might interfere with the inception or distribution of corrosion. The simplest test of a satisfactory surface condition in this respect is for the specimens to be free from 'water break' when rinsed with water after cleaning. As a final treatment for specimens to be weighed prior to exposure, a dip in a mixture of water and acetone or of alcohol and ether will facilitate quick drying and avoid water-deposited films. Specimens to be stored prior to weighing should be placed in a desiccator, which, in best practice, should be sealed without grease.<sup>3</sup>

In addition to the preparation of the principal surfaces of the specimen, it is essential to machine or grind any cut or sheared edges, since these could become sites of preferential attack. As a general rule, edge effects should be kept to a minimum by using specimens in which the ratio of surface area to edge area is large. With flat specimens, a disc is best from this point of view, but other shapes may be more convenient and acceptable in many practical instances. When mass loss is to be used as a measure of corrosion, precision will be improved by providing a large ratio of exposed area to mass, and thin flat specimens or fine wires have obvious advantages. (Wires also have the disadvantage of a metallurgical structure that is usually not typical of bulk material.)

For accuracy of weighing, it is usually necessary to restrict the dimensions of specimens to what can be accommodated on the common analytical balances. It must be borne in mind that where attack occurs in the form of a very few pits or in crevices under supports, the extent of this localized attack may be determined by the total area of the test-piece as it establishes the area of passive metal acting as a cathode to the few anodic areas. Thus, larger specimens, or the much larger surfaces that will often be involved in field or service tests, may give rise to much more severe localized attack under nominally the same conditions of exposure.

In certain tests, it is sometimes desirable to eliminate any effects of a mechanically achieved surface

condition by chemical treatment or pickling of the surface prior to test. This may be done in a pickling solution; alternatively, the test itself may be interrupted after sufficient corrosion has occurred to remove the original surface, the specimen then being cleaned and reweighed and the test started over again. Wesley<sup>4</sup> found it to be desirable to pickle off about 0.008 mm from the surface of specimens in acid to improve the reproducibility of the tests.

With materials the stainless steels that may be either active or passive in a test environment, it is common practice to produce a particular initial level of passivity or activity by some special chemical treatment prior to exposure. With stainless steels this objective may be subsidiary to eliminating surface contamination, such as iron from processing tools, by treatment in a nitric acid solution, which might also be expected to achieve substantial passivity incidental to the cleaning action (ASTM A 380).

In studies of the behavior of materials that may be either active or passive in the test environment, there would seem to be a real advantage in starting with specimens in an activated state to see whether they will become passive, and to ascertain how fast they are corroded if they remain active. If passivity should be achieved after such an activated start, the material can be considered to be more reliable in the test environment than would be the case if by chance it managed to retain an originally induced passivity for all, or most of, the test period. It may also be valuable to know how fast the metal will be corroded by the test medium if activity should persist.

A procedure for testing previously activated specimens applied in studies of titanium was described by Bayer and Kachik.<sup>5</sup> Renshaw and Ferree<sup>6</sup> also employed prior activation in their studies of the passivation characteristics of stainless steels.

In many cases, there is a need to test metal-coated specimens, for example, galvanized steel, tin-plated copper, nickel-plated zinc, etc. It will then be necessary to test specimens in the completely coated condition and also with the coating damaged so that the basis metal is exposed. The latter condition will provide the conditions for galvanic action between the coating and the basis metal. With sheet specimens, this condition is most readily achieved by leaving cut edges exposed to the test environment.

There may also be a need to consider the performance of pre-corroded test specimens. Apart from the fact that these conditions frequently arise in service, it is also important for other reasons:

- The presence of corrosion products or other surface layers may affect the access of constituents of the environment to the underlying metal surface where the corrosion process occurs.
- In the case of alloys, some precorrosion may lead to compositional changes in the surface.

(Additionally, in the case of inhibitor tests, preexisting corrosion product often absorbs a significant proportion of the inhibitor, leading to a lower inhibition efficiency than for a clean surface.) These factors should be taken into account in the application of any test method.

#### **2.34.2.2 Marking Specimens for Identification**

The simplest way to identify a specimen is to mark it with letters or numbers applied by stamping with a stencil or number punch. (Both of these methods have potential problems – in the case of stenciled identification the paint used may act as a crevice-former, while stamping leads to an area of higher plastic strain, which may modify its corrosion behavior.) There is, of course, always the danger that the identification marks will be obliterated by corrosion. To guard against this, the several specimens in a test should be identified further by a record of their positions relative to each other or to their supporting device. Before specimens are taken from test, their identity should be established in this manner unless inspection has already shown that the identification marks have been preserved.

Other means of identification can be used on specimens exposed to atmospheric corrosion. For example, where stamped letters cannot be expected to persist, identification may be provided by holes drilled in particular positions or by notching the edges of specimens in particular places, both in accordance with a template. Where severe corrosion is encountered, the identification by drilled holes is more permanent than that achieved by notching edges.

Other means of identification sometimes used satisfactorily involve chemical etching of the surface (not to be generally recommended), or the formation of letters or numbers by means of a vibrating stylus. The former is advantageous in studies of stress-corrosion cracking, in which stamped symbols could lead to regions of stress concentration.

#### **2.34.2.3 Number of Replicate Specimens**

Practical considerations usually limit the number of replicate specimens of each kind that can be exposed

for each period of test. At least two are recommended for obvious reasons, and if a larger number can be accommodated in the program more valuable results can be secured – especially when it is desired to establish the reality of small differences in performance. For statistical analysis, five replicates are desirable. Accounts of statistical planning and analysis are given by F. H. Haynie in Ailor<sup>2</sup> and in ASTM G 16.

In providing replicates for tests to be subjected to statistical analysis, it is necessary, in the original sampling of the materials to be tested, to ensure that normal variations in those qualities of the metals that might affect the results are represented in each set of samples.

In order to secure information as to changes in corrosion rates with time, as in atmospheric exposure tests, it is necessary to expose sufficient specimens to allow sets to be taken from test after at least three time intervals.

For preliminary tests where the number of test specimens that can be accommodated is limited, yet numerous materials are of possible interest, it is in order to expose single specimens. This may be more advantageous than limiting the compositions that can be investigated by exposing half the number of materials in duplicate. Probably the greatest advantage in exposing two specimens of a material instead of only one is in detecting gross errors, as in weighing, etc. rather than in any considerable improvement in the precision of the observations that may be made as to the relative behaviors of the metals tested.

#### **2.34.2.4 Test of Fusion Welds**

In view of the widespread use of welded joints in equipment and structures exposed to corrosion, it is necessary to know whether such welded joints will demonstrate satisfactory resistance to attack. It is not necessary to include welded specimens of all materials in a preliminary study to discover which of them have satisfactory resistance to a particular environment. Weld tests can be postponed until the preliminary selection has been made, or alternatively, those materials expected in advance to be most likely to be resistant can be exposed in the welded condition to expedite the final answer.

There are several reasons for testing welded specimens. The first is to discover whether the weld itself will resist corrosion satisfactorily. A second purpose is to discover whether the heat effects associated with welding operations have been in any way detrimental to the corrosion resistance of the parent metal near the

weld as in the case of the so-called 'weld decay' of stainless steels. Since weld deposits may themselves be subject to a weld thermal cycle, it is necessary to include cross welds in the design of welded specimens for such corrosion tests. Further, a weld will generally constitute a stress concentration, and unless postweld heat treated, will contain residual contraction stress. Thus, testing may be necessary to generate appropriate corrosion fatigue or stress-corrosion cracking data. The latter may follow ASTM standard G 58, 'Standard Practice for the Preparation of Stress-Corrosion Test Specimens for Weldments,' for example.

A weld bead included in a test-piece is, to some extent, peculiar to itself and may not necessarily be representative of nominally similar welds to be made by other welders under other circumstances. To this extent, results of tests on welds must be subject to some qualification in interpretation, having in mind that what will be disclosed principally will be the overall ability of the composition of the weld metal to resist the corrosive environment. In some cases, entrapped flux, craters, fissures, folds, surface oxides, etc. may introduce localized corrosion that may or may not occur with all welds of the type studied.

The heat effects of welding are to an even greater extent peculiar to the particular test specimens used. They will be influenced by the welding process, by the skill of the welder, by the thickness of the metal welded, by the type of joint made, and by the geometry and mass of the surrounding structure insofar as they affect heating and cooling rates and areas over which these effects apply. Consequently, what happens to a particular welded test-piece has a questionable general significance, especially when the result shows no apparent damage to a material known to be susceptible to welding heat effects in corrosive environments. It should not be assumed that high heat input during welding will represent the worst case. For example, with ferritic steels that are sensitive to hydrogen embrittlement stemming from environmental action, low welding heat input can be most detrimental because of the formation of hardened structures in the weld area. Moreover, the possible effects of multipass welding with attendant repeated thermal cycles must be recognized in the design of a suitable test-piece.

With some materials, there are specific heat treatments that are known to reproduce the worst effects of the heat of welding. It is recommended, therefore, that in tests made to qualify a material for a particular service environment, in addition to the exposure of welded test specimens in order to observe effects of

welding heat, specimens that have been given a controlled abusive or sensitizing heat treatment should be included. As an illustration, austenitic stainless steels may be held at 650–700 °C for 0.5–1 h, followed by testing for susceptibility to intercrystalline attack as in ISO 3651-1 or-2.

If such sensitized specimens remain as free from accelerated corrosion as the welded specimens do, then it can be concluded that no detrimental effects of the heat of welding need to be anticipated in the environment covered by the test. However, if the sensitized specimens are corroded while the welded specimens are not, there will remain the possibility that, under some conditions of welding, difficulties due to the effects of the welding heat may be encountered, and appropriate action or the substitution of more reliable compositions will be required. Having in mind the effect of time in damage of this sort, it will be necessary to make a careful examination of the corroded specimens to detect the first signs of attack before it can be concluded that none has occurred. In assessing the significance of attack observed on drastically sensitized specimens, it is necessary to keep in mind that no similar sensitization may result from good welding practice. Likewise, it should not be concluded that attack in a specific test environment will occur to a similar extent or will not occur at all, in some quite different environment.

The evaluation of heat treatments or the effectiveness of stabilization by limiting carbon content of these stainless steels can be determined by subjecting specimens to the ASTM standardized acid copper sulfate test or boiling nitric acid test (ASTM A 262).

#### 2.34.2.5 Duration of Exposure

The duration of a particular test is likely to be determined by practical factors such as the need for some information within a particular limit of time, or the nature of the operation or process with which the test is concerned. Tests are rarely run too long; however, this can happen, particularly in laboratory tests where the nature of the corrosive environment may be changed drastically by the exhaustion of some important constituent initially present in small concentration, or by the accumulation of reaction products that may either stifle or accelerate further attack. In either case, the corrosivity of the environment may be altered considerably. Gross errors may result from the assumption that the results apply to the original conditions of the test rather than to

some uncertain and continually changing conditions that may exist during the course of too extended a test period.

Rates of corrosion rarely remain constant with time. More often than not, rates of attack tend to diminish as a result of the formation of adherent insoluble corrosion products or other protective films originating in the environment (Figure 1). Therefore, extrapolation of results of tests that are too short is more likely to indicate a lower resistance to attack than will actually be observed over a prolonged period of exposure. To this extent, such extrapolation may be considered as conservative. At the worst, it may lead to the use of a more resistant material or a heavier section than is actually needed, or to the exclusion from consideration of some materials that might be much better than the short-time test results would indicate.

Tests should be of sufficiently long duration to permit demonstration of the possible protective nature of films. Lengthy tests would not normally be required for materials that experience severe corrosion, although there are cases where this is not so. For example, lead exposed to sulfuric acid corrodes at an extremely high rate initially, while building up a protective film, then the rate decreases considerably and further corrosion is negligible. Short tests on such materials would indicate a high corrosion rate and would be completely misleading. Short-term tests can also give misleading results on alloys such as stainless steels that form passive films. With borderline conditions, a prolonged test may be needed to permit breakdown of the passive film and the subsequent more rapid attack. Consequently, tests run for long periods are considerably more realistic than those conducted for short periods.

**Figure 1** Corrosion rate vs. time curve showing diminishing rate of attack. Reproduced from *Proc. ASTM* 1951, 51, 500.

Where anticipated corrosion rates are moderate or low, ASTM G 31 suggests that the following equation be used to estimate a suitable test duration:

$$\text{Test duration (h)} = 50 / (\text{Corrosion rate, mm year}^{-1})$$

For example, where the corrosion rate is 0.25 mm year<sup>-1</sup>, the test should run for at least 200 h.

Due to the relatively slow rate of the atmospheric corrosion process, it is recommended in ISO 8565 that test exposures be on a schedule such as 1, 2, 5, 10, and 20 years, depending on the corrosion resistance of the metal or coating being tested. In some cases, a total exposure of less than 2 years may be suitable. It should be noted that, especially for short-term testing, the results may depend on the season of initiation of exposure. Therefore, it is recommended that exposures are commenced in the period of highest corrosivity (usually autumn).

Tests in waters and soils should ordinarily be allowed to run for extended periods in excess of 3 years, with removals of specimens in groups after different time intervals. A desirable schedule for any extended test in a natural environment is one in which the interval between successive removals is doubled each time. For example, the first removal would be after 1 year, the second after 3 years, and the third after 7 years, and so on. On the other hand, test periods should not be significantly longer than the process or exposure time of the end-use requirement. The testing of inhibitors for use in pickling or cleaning treatments should be of a period commensurate with the practical requirement, which may be for only a few minutes.

In any event, the actual duration of a test must be reported along with the results, so that those who may wish to make predictions based on them will have an accurate idea of the extent to which they may undertake any extrapolation or interpolation.

#### 2.34.2.6 Heat Treatment

Many alloys are subject to drastic changes in their response to the effects of corrosive media when they have undergone certain heat treatments. The principal effect of interest is a loss of corrosion resistance to some degree. This commonly takes the form of concentration of corrosion in particular regions or along certain paths – as in the vicinity of grain boundaries – where phases formed by heat treatment are most likely to be concentrated. In other instances, and particularly in castings, homogenizing heat treatments may improve corrosion resistance by

eliminating 'coring' or major differences in composition from point to point in the original dendritic cast structure. Heat treatments that eliminate internal stresses are obviously helpful in connection with stress corrosion, but may induce structural changes that can affect corrosion in other forms.

Heat treatments involving heating to a temperature high enough to take harmful phases into solution, followed by cooling (e.g., by quenching) at a rate high enough to hold such phases in solution, may also be helpful in improving resistance to corrosion by avoiding attack that would otherwise be associated with a precipitated phase or compound.

Obviously, some knowledge of the possible effects of such heat treatments is essential for a complete understanding of the corrosion behavior of an alloy. Studies along this line should follow the initial selection of a material considered to be possibly useful for a particular service. Thus, it should be tested in the condition most likely to resist corrosion. Sometimes the obtaining of this condition may require annealing at a temperature sufficiently high to take any possibly harmful phases or compounds into solution followed by quenching to prevent them from precipitating. Following this preliminary selection, it would be prudent to carry out additional corrosion tests on specimens that have been deliberately subjected to any possibly detrimental heat treatments to which the material may be subjected during processing, fabrication, or use.

Heat treatment may also affect the extent and distribution of internal stresses. These may be eliminated by appropriate annealing treatments that can remove susceptibility to stress-corrosion cracking. This must be explored in any study of the performance of materials in environments where stress-corrosion cracking is a hazard. In particular cases, stress-relief annealing treatments may result in the appearance of new phases that, while eliminating the stress-corrosion effects, will induce another type of path of attack. This possibility must be kept in mind in assessing the overall benefits of heat treatments applied primarily for stress relief.

In other instances, heat treatments involving quenching, tempering, or holding at some temperature to precipitate an age-hardening compound are employed to secure some desired level of hardness or other mechanical properties. It is obviously necessary to explore what effects such heat treatments may have on the corrosion resistance of the material in the condition, or conditions, of heat treatment in which it is to be used.

### 2.34.2.7 Stress Effects

Techniques for studying the effects of stress on corrosion are covered in some detail elsewhere in this work. So far as attention to stress effects in a general materials-selection program is concerned, it is suggested that this should be a supplement to the initial selection of processing materials by exposing specimens to what approaches their best condition to resist corrosion, that is, free from stresses. Materials found to be worthy of further consideration in this way can be subjected to tests for stress effects. Where it is desired to discover whether severe internal stresses can be satisfactorily accepted, it will suffice to expose specimens in such a condition of stress. For example, a crucial test can be made by using a specimen in the form of a heavily cold-drawn tube in the as-drawn condition flattened on one end to introduce some additional multiaxial stresses. If such a severely cold-worked specimen suffers no stress-corrosion cracking in a test, then the danger of this occurring on any structure of that metal in the environment represented by the test is extremely remote.

### 2.34.2.8 Appraisal of Damage

There are many ways of determining the extent or progress of corrosion. The choice may be determined either by convenience or on the basis of some special interest in a particular result of corrosion or in a particular stage of a corrosion process.

Probably the most frequently made observation is the change in mass of a test-piece. This may take the form of a mass gain or a mass loss.

Mass-gain determinations are most common in studies of the extent and rate of oxidation or scaling at elevated temperatures. Very precise studies of this sort can be made by continuous observation of mass changes, as in the use of microbalances, such as used and described by Gulbransen.<sup>7</sup> Such data have quantitative significance only when the exact composition (metal content) of the scale is known or can be determined and when there has been no loss of loose scale during or after the test. Fundamental studies of the initial stages of corrosion when films of a few monolayers are formed have made use of an ellipsometer to follow the increase of thickness of corrosion products without disturbing the specimen.<sup>8</sup>

In most other cases, data on gains in mass due to the accumulation of corrosion products have little quantitative significance, since there is usually a question as to how much of the corroded metal is

represented in the corrosion products that remain attached to the specimen at a particular time. There are also uncertainties as to the chemical composition of corrosion products, which may consist of mixtures of several compounds with varying amounts of combined or uncombined water, depending on the humidity of the atmosphere at the time.

For these reasons, it is much better to determine the amount of metal removed by corrosion by weighing what is left after the removal of all adherent corrosion products by some method that will not cause further attack in the process, or by making proper correction for losses in the cleaning process. (Removal of corrosion products is dealt with in detail in [Appendix A](#).) Subtracting this final mass from the original mass will give the loss in mass during the test. Since the extent of this loss in mass will be influenced by the area exposed, as well as by the duration of exposure, it is desirable, to facilitate comparisons between different tests and different specimens, to report the loss in mass in a unit that includes both area and time. A most commonly used unit of this sort is milligrams weight loss per square decimeter of exposed surface per day (24 h) (mdd).

The unit gram per square meter per annum (gma) is sometimes used in atmospheric corrosion tests (see ISO 9226) where 'a' represents 'year.' It must be recognized that these units embody two assumptions that may not, in fact, be true. The first is that corrosion has occurred at a constant rate throughout the test period. This is rarely the case, since most rates of attack tend to diminish with time, but if the duration of the test and the actual loss in mass are also reported, the user of the data can take this into account. The second probable error in a mass loss/unit area unit is that it implies that corrosion has proceeded uniformly over the whole surface. These units, therefore, will give the wrong impression as far as the probable depth of attack is concerned, if corrosion has occurred at only a few spots on the surface of the specimen. Obviously, the mdd and gma units have limited significance when corrosion has taken the form of scattered pits or has been confined to the crevices where the specimen was supported. This should be covered by appended notes describing the nature and location of the corrosion represented and should be supplemented by data on the actual depths of the pitting or crevice attack. Here, again, the report should include data on the actual mass losses and duration of exposure.

Expression of mass loss in terms of a percentage of the original mass of a test-piece is usually

meaningless except for comparing specimens of the same size and shape, since it does not take into account the important relationship between surface and mass.

As indicated, it is necessary to measure and report the depths of any pitting or other localized corrosion, such as in crevices, that may have occurred. It is also useful to provide information on the frequency of occurrence, distribution, and shape of pits, since these features are likely to have practical significance. Champion<sup>1</sup> has produced charts in which the number of pits/unit area, the size of pits, the depth of pitting, cracking, and general attack can each be rated by the numbers 1–7. Where the number of pits is very large, it is obviously impracticable to measure the depths of all of them. Consequently, the practice of choosing 10 of the deepest pits and reporting their average depth and that of the deepest of them has developed. All surfaces of the specimen should be examined in selecting the 10 deepest pits.

There are several ways of measuring pit depths, but in all cases these measurements are facilitated if corrosion products are first removed (see [Appendix A](#)). If the pits are large enough, their depths may be measured directly with a pointed micrometer or with an indicating needle-point depth gauge. Otherwise, they may be measured optically with a microscope by focusing in turn on the surface of the specimen and, on the bottom of the pit using a calibrated wheel on the fine-focus adjustment rack for this focusing operation. In some instances, the small dimensions or shapes of pits may require metallographic examination of a cross-section for a precise measurement of depth. Such metallographic examination may also be useful in detecting an association of pitting with a structural feature of the metal.

Since it is often difficult to visualize the extent of attack in terms of depth from such mass-loss units as mdd, it is common practice to convert these mdd figures into others to indicate depth of penetration, for example, millimeter per year or mils per year (mpy), where 1 mil = 0.001 in. Such calculations suffer from the same defects as the mdd figures in that they take into account neither changes in corrosion rates with time nor nonuniform distribution of corrosion. However, since such conversions are often made, it is desirable for the initial reporter of the test results to make the calculations accurately and to report corrosion rates in both mdd and  $\text{mm year}^{-1}$  or similar units.

The basic formula for making such calculation is:

$$\text{mdd} \times 0.0365/\rho = \text{mm year}^{-1}$$

where  $\rho$  is the density of the metal ( $\text{g cm}^{-3}$ ). Some values showing the relationship between mdd, and mpy and  $\text{mm year}^{-1}$  are given in Table 1.

Losses in mass will also not disclose the extent of deterioration that may result from the distribution of a very small amount of attack concentrated along grain boundaries or in transgranular paths (as in some cases of stress-corrosion cracking). In such instances, an apparently trivial or even undetectable loss in mass may be associated with a practically complete loss of the strength or ductility of the corroded metal. Where this may be suspected, or in any doubtful cases, the mass-loss determinations must be supplemented by other means of detecting

this sort of damage, including simple bend tests followed by visual or metallographic examination to disclose surface cracking, quantitative tension tests, and direct metallographic examination of cross-sections. Changes in electrical resistance have been used as a measure of intergranular attack.<sup>9</sup> Because of the nature of such resistance determinations,<sup>10,11</sup> they have been more useful for comparing specimens of a particular kind and size than as a basis for quantitative expression of rates of attack.

The characteristic mode of corrosion of some alloys may be the formation, as a corrosion product, of a redeposited layer of one of the alloy constituents, as in the case of the brasses that dezincify, or of a residue of one of the components, as in the case of the graphitic corrosion of cast iron. Particularly in the case of the dezincified brass, the adherent copper is not likely to be removed with the other corrosion products, and therefore, the mass-loss determination will not disclose the total amount of brass that has been corroded. This is especially important because the copper layer has very little strength and ductility and the extent of weakening of the alloy will not be indicated by the mass loss. In these cases, also, the mass-loss determinations must be supplemented by, or replaced by, mechanical tests or metallographic examination, or both, to reveal the true extent of damage by corrosion. Difficulties in obtaining accurate mass losses of heavily graphitized specimens have been reported.<sup>12</sup>

Whenever changes in mechanical properties, such as performance in tension tests, fatigue tests, and impact tests, are to be used as a measure of corrosion damage, it is obviously necessary to provide test data on the relevant properties of the uncorroded metal. When tests extend over long periods during which the alloys being tested may be subject to changes in mechanical properties due to ageing effects, entirely aside from corrosion, it will be necessary to provide sets of specimens that may be subjected to similar ageing in a noncorrosive environment so that by direct comparison with corroded specimens of the same age the changes due to corrosion can be separated from those due to ageing. Preferably the control specimens should be stored so that they will be subjected to the same thermal experience as the specimens undergoing corrosion. This is usually very difficult to accomplish while maintaining the control specimens completely protected from corrosion.

In calculating the strength properties of the corroded specimens and comparing them with those of the uncorroded control specimens after appropriate

**Table 1** Relationship between corrosion rate in  $\text{mg dm}^{-2} \text{d}^{-1}$  (mdd) and penetration in mpy and  $\text{mm y}^{-1}$

Material	Density ( $\text{g cm}^{-3}$ )	Penetration equivalent to a corrosion rate of 1 mdd	
		mpy	$\text{mm year}^{-1} \times 10^2$

Tin	7.29	0.197	0.500
Zinc	7.15	0.201	0.510

mechanical tests, it will be necessary to take into account the actual area of the cross-section of the corroded metal and report results on this basis instead of, or as well as, on the basis of the original cross-section before exposure, such as would be represented by the uncorroded control specimens.

In view of possible or probable variations in mechanical properties among different specimens of the same metal cut from different sheets or other pieces, or even from different sections of the same sheet or piece, it is necessary to pay careful attention to the initial sampling of stock to be used for control, as well as exposure, specimens. An interesting case in which several of these considerations were involved was provided by the long-time atmospheric exposure tests of nonferrous metals carried out by Subcommittee VI of ASTM Committee B-3 on Corrosion of Non-Ferrous Metals and Alloys<sup>13</sup> in which changes in tensile properties were used as one of the means of measuring the extent of corrosion.

Tests carried out for particular purposes may make use of other special means to measure the progress of corrosion. For example, changes in the reflectivity of polished surfaces<sup>14,15</sup> have been used as a sensitive means of following changes in the very early stages of corrosion in laboratory studies. A similar technique has been applied on a practical scale in connection with the direct evaluation of the relative merits of different alloys as used for mirrors in searchlights exposed to corrosive natural atmospheres.

Kruger,<sup>16</sup> at the then US National Bureau of Standards, used an ellipsometer to follow the growth of very thin corrosion-product films (oxides) during the initial stages of corrosion. This requires a knowledge of the composition of the oxide and its refractive index.

In some cases, the principal interest is in the possibility of undesired contamination or other alteration of an environment rather than in the rate of destruction of the metals being tested. Here, in addition to paying attention to the usual factors that influence rates of corrosion, it is also necessary to consider the ratio of the area of the test specimen to the volume or mass of test solution, and the time of contact. All of these factors may be quite different in a test from what would be obtained in a practical case, and any distortions of the test in these ways must be taken into account in planning the test and in interpreting the results.

In cases such as this, the possible contamination of the solution by corrosion products may be estimated from the loss in mass of the test specimen. This,

however, does not make any distinction between soluble and insoluble corrosion products, which may have different effects and which can be studied best by chemical analysis of the test solution and the materials filtered from it. Similarly, chemical analysis may be required to detect any other changes in the composition of the test solution that may be of interest.

Particularly in theoretical studies of corrosion processes, it has been useful to measure the progress of corrosion in terms of the rate or extent of consumption of oxygen in the corrosion reactions. This technique has been very useful in following the progress of wet corrosion or of oxidation in its initial stages.<sup>17</sup>

Somewhat along the same lines is the measurement of the volume of hydrogen generated as corrosion proceeds.<sup>18,19</sup> This technique has been used not only in theoretical studies, but also as a means of comparing some corrosion-resisting characteristics of different lots of steel that seem to affect their behavior when used as a base metal for tin cans.<sup>20-22</sup>

The polarograph has been found to be a very useful tool for following the progress of corrosion, especially in its early stages, by measuring minute changes in the composition of the solution, as in the consumption of some constituent, such as oxygen, or by the accumulation of metal salts or other reaction products, such as hydrogen peroxide.<sup>23</sup>

An electrical resistance method that directly measures loss of metal from a probe installed in the corrosive system under study is described as follows. It is reported that corrosion equivalent to a thickness loss of as little as  $2.5 \times 10^{-7}$  cm can be detected.<sup>24,25</sup> This technique is most useful as a means of monitoring steps taken to reduce corrosion, for example, by inhibitors, or to detect changes in the corrosivity of process streams. Electrical methods of determining corrosion rates are considered subsequently.

Temperature effects may also be used in test methods, notably for assessing the effects of inhibitors in acid solutions. The technique is based on the one first proposed by Mylius,<sup>26</sup> which records the temperature-time behavior associated with the exothermic reaction resulting from the initial contact of a metal with a corrosive acid solution. The effectiveness of inhibitors may then be determined from their effects on the temperature-time behavior.<sup>27</sup>

#### **2.34.2.9 Removal of Corrosion Products**

An ideal method for removing corrosion products would be one that would remove them completely

without causing any further corrosion or other deterioration of a test specimen in the process. Procedures that achieve this ideal or approach it very closely have been developed for many of the common alloys.

There are numerous satisfactory methods of cleaning corroded specimens, but whatever the method, its effect in removing base metal should be determined for each material<sup>28–30</sup> taking into account possible differences between the behavior of ‘as-new’ and corroded base metal (see [Appendix A](#)). The various methods may be classified as follows:

1. Mechanical treatment:
  - a. scrubbing with bristle brush,
  - b. scraping,
  - c. wire brushing,
  - d. grit, shot, sand blasting;
2. Chemical treatments:
  - a. organic solvents,
  - b. chemical reagents;
3. Electrolytic treatments as cathode in solutions of the following:
  - a. sulfuric acid, usually inhibited,
  - b. citric acid,
  - c. potassium cyanide,
  - d. sodium hydroxide.

Further details of removing corrosion products are given in [Appendix A](#).

## 2.34.3 Laboratory Corrosion Tests

### 2.34.3.1 Total-Immersion Tests

The total-immersion corrosion test is most adaptable to rigorous control of the important factors that influence results. This control may be achieved in different ways and it is unnecessary and undesirable to seek a standardized method or apparatus for universal use. All that is required is a recognition of what is essential, as covered, for example, by the ASTM procedure G 31. This represents a code of minimum requirements without insisting on the use of any particular kind of apparatus or specifying the exact conditions of aeration, temperature or velocity to be used. Since different metals respond differently to effects of aeration, temperature and velocity, the setting up of standard test conditions in terms of these factors would be inappropriate. Depending on the environment, such standardized testing conditions would favor maximum corrosion of some materials and minimum corrosion of others and thus lead to gross errors in indicating any general order of

merit applicable under conditions differing from those of a standardized test.

In some instances, it may be possible, although it is usually very difficult, to undertake laboratory corrosion tests under conditions that will be the same as those encountered in some practical application and thus to secure some directly applicable data. More often, the conditions of service are so variable or so difficult to appraise accurately and duplicate in the laboratory that it is impractical and probably unwise to attempt to do so. A better procedure is to examine the individual effects of the several controlling factors by varying them one at a time so as to provide a picture of their influence on the behavior of the materials of interest in the corrosive medium being investigated. This information will be helpful in deciding whether the conditions of a particular use are favorable or unfavorable to the materials being considered. It will also serve as a guide to account for behavior in service and to suggest changes in the operating conditions that may be expected to reduce corrosion of a material being used.

In many cases, and particularly in aqueous solution, the most important controlling factors will be solution composition, temperature, aeration, and velocity.

#### 2.34.3.1.1 Solution composition

When designing tests to determine the effects of solution composition on corrosion, it is important to understand the nature of the controlling process. In the case of many metals and alloys, the rate-determining step will be the supply of cathodic reactant to the metal surface. This is particularly true in neutral solutions where corrosion will often be under oxygen diffusion control. Thus, tests in stagnant (unstirred, quiescent) conditions may be inappropriate, since the effects of solution composition will be insignificant compared with the oxygen diffusion effect. In stagnant conditions, corrosion rates of mild steel in, for example, sodium chloride, sodium sulfate and other salt solutions will be effectively the same over a range of concentrations. The effects of anion type and concentration begin to be shown only with movement of the solution, that is, when oxygen access to the metal surface is facilitated to the point where it may be no longer rate controlling. Specific effects of anions in stagnant solutions will, however, be found when the anion has oxidizing properties, as in the case of nitrate and in systems where the dominant cathodic reaction is hydrogen evolution.

Care must therefore be taken in designing tests to study the effects of solution composition since

different results will be obtained depending on the degree of aeration and/or movement of the solution.

Variations in solution composition throughout a test should be monitored and, if appropriate, corrected. Variations may occur as a result of reactions of one or more of the constituents of the solution with the test specimen, the atmosphere or the test vessel. Thus, it is important that the composition of the testing solution is what it is supposed to be. Carefully made-up solutions of pure chemicals may not act in the same way as nominally similar solutions encountered in practice, which may, and usually do, contain other compounds or impurities that may have major effects on corrosion. This applies particularly to 'artificial' seawater, which is usually less corrosive than natural seawater. This subject is discussed in detail in a Special Technical Publication of ASTM,<sup>31</sup> and tests with natural, transported, and artificial seawater have been described.<sup>32</sup> Suspected impurities may be added to the pure solutions in appropriate concentrations or, better still, the testing solutions may be taken directly from plant processes whenever this is practical.

It should also be pointed out that in exploring the effects of the concentration of a particular acid or other chemical on its corrosivity, it is necessary to cover the full possible variation of concentrations thoroughly, since it frequently happens that particular ranges of concentration are especially corrosive to some metals. This extends to the highest degrees of concentration where sometimes the complete elimination of water may increase corrosion a great deal – as in the case of aluminum in acetic acid. On the other hand, the presence of a trace of water may make other chemicals much more corrosive – as in the case of bromine and other halogens.

It should be noted, also, that exposing a specimen to a solution of some chemical while it is being concentrated by evaporation practically to dryness will not suffice to explore the effects of the complete range of concentration, simply because the period in which any particular concentration range exists is not likely to be long enough to permit any especially corrosive effects to be detected in the overall result.

#### 2.34.3.1.2 Temperature control

Of the factors mentioned, temperature is probably the easiest to control; this can be accomplished by means of a thermostat or by operating at the boiling point of the testing solution with an appropriate reflux condenser to maintain the solution at a constant concentration. Control to  $\pm 1^\circ\text{C}$  is not hard to accomplish.

The need for temperature cycling should be taken into account when designing or conducting tests. The nature of the test vessel should be considered for tests in aqueous solutions at temperatures above about  $60^\circ\text{C}$  since soluble constituents of the test vessel material can inhibit or accelerate the corrosion process. An inhibiting effect of soluble species from glass, notably silica, on the behavior of steel in hot water has been shown.<sup>33</sup> Pure quartz or polymeric materials are often more appropriate for test vessel construction. (It should also be recognized that the control of gas concentrations becomes more difficult as temperature approaches the boiling point of the solution.)

#### 2.34.3.1.3 Aeration

Control of aeration is more difficult. Aeration here means the amount of oxygen supplied either as such or, more commonly, in air. In some situations, it may not require a large amount of air bubbled through a solution to accommodate even a modest rate of corrosion of a small test-piece. Figure 2 shows the relationship between the rate of supply of air used for aeration and the rate of corrosion of Monel alloy in 5% sulfuric acid.

To facilitate rapid solution of oxygen from air bubbles it is desirable to make these as small as possible, for example, by having the air enter through a porous thimble or sintered glass disc. Much less satisfactory results are secured by simply letting air escape into the solution from a tube drawn to a fine tip.

It is also undesirable to permit air bubbles to impinge directly on the test-pieces. This can be avoided by placing the aerator inside a chimney.

When it is desired to study effects of various degrees of aeration, it is better to do this by varying the oxygen content of the saturating gas (e.g., by using controlled mixtures of oxygen and nitrogen)

**Figure 2** Effect of rate of supply of air used for aeration on corrosion of Monel alloy in 5% sulfuric acid.

introduced at a constant and adequate rate than by attempting to vary the rate of admission of a gas (such as air) of constant composition. This extends as well to zero aeration, which can best be accomplished by saturating the test solution with deoxygenated nitrogen or other inert gas. It is unwise to assume that, because no air is purposely added, oxygen has been excluded from a test solution in a vessel open to air. Such a practice provides a low oxygen availability that is not sufficiently under control to ensure reproducible results.<sup>3</sup>

#### 2.34.3.1.4 Velocity

Controlled flow conditions can be achieved either by having the test-piece move through a notionally stationary liquid or by having a moving liquid come into contact with a stationary test-piece. Occasionally tests may involve both types of exposure. Details of test procedures are presented elsewhere.

The achievement of zero velocity in a test set-up is about as difficult as the accurate control of some high velocity. It is a common mistake to assume that by not making any attempt to move either the specimen or the testing liquid, the relative velocity between them will be zero. This neglects such effects as convection currents and the agitation due to the effects of corrosion products streaming under the influence of gravity. The most common difficulty arising from this situation is that these uncontrolled effects in tests made under presumably quiet or stagnant conditions make it very difficult to secure reproducible results from test to test. Therefore, even when there is no practical interest in the effects of any appreciable velocity, it is desirable to provide for some controlled movement of either the specimens or the solution at some velocity such as  $7.5 \text{ cm s}^{-1}$ , readily achieved with a vertical circular-path machine.

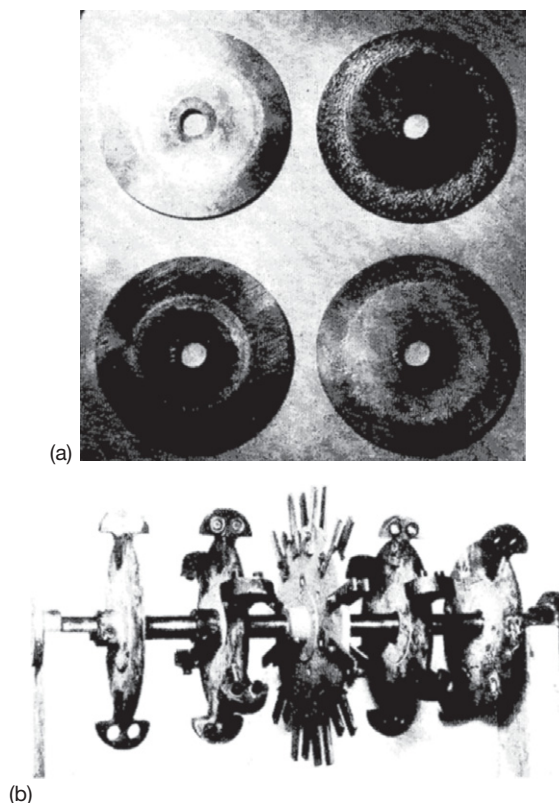

Equipment of this type in which the specimens are moved in a vertical circular path with all portions of the surface of a specimen moving at the same speed has been used in instances where such moderate test velocities are required. Statistical analysis of data from tests with an apparatus by Wesley<sup>4</sup> has demonstrated satisfactory reproducibility of results not only among specimens in a particular test, but also from test to test undertaken at different times.

Where effects of much higher velocities are to be studied, various devices have been used to move test-pieces through the testing solution at high velocity.

One procedure is to use test specimens in the form of discs, which can be rotated at the desired speed while either wholly or partly immersed in the testing

solution, and Freeman and Tracy described a device of this sort in a contribution to the ASTM Symposium on Corrosion Testing Procedures.<sup>28</sup> With their apparatus the specimen discs were mounted on horizontal shafts and were partially immersed in the testing solution.

A similar method of test was used at the International Nickel Company's Corrosion Laboratory at North Carolina. The specimen discs are mounted on insulated vertical spindles and submerged in seawater, which is supplied continuously to the tank in which the specimens are immersed. The maximum peripheral speed of the spinning disc is about  $760 \text{ cm s}^{-1}$ , and the characteristic pattern of attack is shown in **Figure 3(a)**. Studies of variation of depth of attack with velocity indicate that at low velocities (up to about  $450 \text{ cm s}^{-1}$ ) alloys such as Admiralty brass, Cu-10Ni and cupronickel alloys containing iron maintain their protective film with a consequent small and similar depth of attack for the different alloys. At higher velocities the rate increases due to breakdown of the film.

**Figure 3** (a) Distribution of corrosion on surfaces of rotating disc specimens and (b) assembly of specimens attached to rotating discs.

Tests of this sort indicate a sort of critical velocity for each material that marks the boundary between the maintenance and loss of protective films. These apparently 'critical' velocities must be considered as relative and only applicable to the conditions of test in which they are measured. Because of the complex effects associated with the differences in velocity from point to point on such rotating specimens, the apparent 'critical velocity' obtained in a given test may be quite different from what might be indicated by another test in which the same velocity is achieved in some other way – as by moving the liquid past a stationary specimen at a uniform velocity from point to point. The apparent 'critical velocity' indicated by this latter method of test will likely be higher for many materials than that shown by the spinning disc test. Thus, the establishment of critical velocities by a particular method of test will afford only qualitative data regarding the relative abilities of a number of materials to resist the destructive effects of high velocity. Furthermore, the critical velocity at which severe attack commences has been found to depend on the diameter of the disc so that no quantitative significance can be attached to it. This restriction extends as well to tests with iron discs, where attack is concentrated at the centre of the disc rather than at the periphery, irrespective of its diameter. (Small variations in solution composition may also affect the value of any critical velocity. In laboratory tests using recirculating artificial seawater the presence of dissolved copper from copper alloy test-pieces has been shown to affect the critical velocity for such materials.)<sup>34</sup>

Somewhat similar tests may be made by attaching specimens to discs that can be rotated at some desired velocity in the testing medium. A machine of this sort that is used extensively in studying corrosion of metals by seawater at high velocity was developed by the staff of the US Naval Engineering Experiment Station at Annapolis, Maryland.<sup>35</sup> A typical assembly of discs and specimens is shown in **Figure 3(b)**.

The action of the rotating discs with their attached specimens causes violent agitation of the liquid in the tank. Depending on the height of liquid above the specimens, as determined by the location of the overflow pipe, there may be considerable whipping of air bubbles into the liquid or none at all, as desired. The heat of agitation causes the temperature to rise. This may be controlled readily by adjusting the amount of fresh cold liquid, for example seawater, allowed to pass into the tank and out through the overflow pipe. It is not difficult to hold the temperature within 1–2 °C of the desired value.

The use of rotating discs to carry test specimens has been extended to studies of protective coatings in what are considered to be 'accelerated' tests of such coatings for service underwater.<sup>36</sup>

Velocity effects involving a high differential in velocity between adjacent areas are achieved simply by exposing a test specimen to the action of a submerged jet. This sort of test has been very popular and very useful in studying impingement attack or erosion of condenser tube alloys. It was introduced originally by Bengough and May<sup>37</sup> and later modifications were described subsequently by May and Stacpoole.<sup>38</sup> The appearances of typical specimens from this test are shown in **Figure 4**. In this test the dimensions of test specimens should be standardized, since the depth of attack has been found to be influenced by the extent of the immersed area of the specimen that is outside the impingement zone.

Along the same general lines is an apparatus employed by Brownsdon and Bannister<sup>39</sup> in which a stream of air at high velocity is directed against the surface of a submerged test specimen.

A straightforward way to study velocity effects is to force the testing liquid through tubular specimens, which may be arranged to form model piping systems for studying the peculiar corrosion that may result from severe turbulence effects downstream of valves, reducers, branch connections, elbows, and other fittings. In such systems the rates of flow can be measured by suitable orifice meters and regulated by control valves. A somewhat similar technique applied to condenser-tube alloys is to test them as installed in model tube-bundle assemblies.<sup>40</sup> Butler and Ison have described a laboratory test rig for studying the effects of flowing water on steel pipework.<sup>41</sup>

Other methods involve holding specimens in suitable fixtures so that they form the walls of channels through which the test solution can be passed at controlled rates of flow. Such devices have been used at the Harbor Island Test Station in North Carolina primarily for studying the electrode potential and polarization characteristics of metals and alloys, but they are also suitable for observing effects of velocity on corrosion. This is illustrated in **Figure 5** in which the specimen and Pt electrode are of the same size and are placed parallel to one another in the holder. When required potentials are measured by inserting a capillary through the hole in the Pt, it is removed to avoid shielding effect.

Effects of velocity are sometimes aggravated by the presence of abrasive solids in suspension, which increases deterioration by straight mechanical abrasion as well as accelerating corrosion by continually

**Figure 4** (Top) Pattern of corrosion of jet-impingement test specimens and (bottom) sample test data and results.

**Figure 5** Components of apparatus in which specimens form walls of channel for test solution.

exposing fresh surfaces to attack. Such attack is especially serious with pumps, agitators, and piping systems. Special apparatus has been designed to measure the performance of materials under such conditions, as described, for example, by Fontana.<sup>42</sup>

Special devices have been used to study erosion-corrosion by boiler water moving at high velocity, and an example is the method used by Wagner *et al.*<sup>43</sup>

Where high rates of flow are desired with a small volume of testing liquid, a specimen may be mounted in the form of a tube inside a large glass tube and a small mass of liquid may be forced to flow through the restricted annular space between the two tubes. Such a method was used successfully in

studying corrosion by milk where the volume of milk was small, the required movement being achieved simply by the use of an air lift to return the milk to an overhead reservoir from which it flowed by gravity through the test set up.<sup>44</sup> Velocities as high as  $0.6 \text{ m s}^{-1}$  were studied in this way.

#### 2.34.3.1.5 Volume of testing solution

If exhaustion of corrosive constituents that may be present in minute concentrations and the accumulation of reaction products which may either accelerate or stifle further attack are to be avoided, the volume or mass of testing solution must be sufficiently large to avoid effects caused by these factors. In laboratory tests, however, practical considerations limit the volume of testing solution that can be provided for. A minimum of 250 ml of testing solution for each  $6.3 \text{ cm}^2$  of specimen area is suggested in NACE TM0169.

#### 2.34.3.1.6 Support of specimens

Since crevices set up where specimens are in contact with their supports and may become the seats of accelerated corrosion by concentration cell effects, special attention should be given to this detail in setting up tests. The area screened by the supporting members should be kept to a minimum, for example, by making contact at a point or along a line rather than over any appreciable area. In some instances it may be desirable to apply some protective coating to the areas that are in contact with the supporting members. In any event, any corrosion that has occurred in the area of the supports should be taken into account in appraising and reporting the results of a test.

Somewhat along the same lines are techniques that have been employed to avoid edge effects by having the specimen come into contact only with a pool of testing solution, which does not cover its complete surface – as described, for example, by Brenner.<sup>45</sup> A more elaborate technique in which the pool of testing solution was circulated by thermal currents was described by Smith.<sup>46</sup>

#### 2.34.3.2 Alternating-Immersion Tests

One means of ensuring aeration of a testing solution in contact with a specimen is provided by an alternating-immersion corrosion test in which the specimen is alternately immersed in a solution and withdrawn from it in some predetermined cycle. This procedure also has the effect of allowing the test solution that clings to the specimen to become concentrated by evaporation while the specimen is out of the liquid,

and in addition it permits corrosion products to remain and reach greater concentrations and undergo more chemical changes in immediate contact with the metal than can occur in continuous-immersion tests. In these ways, an alternating-immersion test may simulate certain circumstances of practical corrosion better than a continuous-immersion test and may, therefore, be preferred.

Since the conditions of this test can be standardized fairly readily, it has also been used as a routine test in comparing different alloys of the same general kind in the course of studies of effects of composition on properties, as, for example, in the researches by Hanawalt *et al.* on the corrosion of magnesium.<sup>47</sup>

The ASTM have established a recommended procedure for alternating-immersion stress corrosion tests in 3.5% NaCl solution (ASTM G 44).

The alternating immersion may be accomplished either by moving specimens held in a suitable suspension rack into and out of containers holding the test solution, by leaving the specimens fixed and raising and lowering the solution containers around them so as to immerse them or leave them suspended above the solution, or by using a combination of pump and siphon to move the solution between two reservoirs.

To favor reproducibility of results, the cycles of immersion and withdrawal must be kept the same from test to test. It is necessary to control the temperature and humidity of the atmosphere surrounding the test setup as these affect the rate of evaporation of the solution and of drying of the specimens when they are out of the solution. It is also necessary to provide for replenishing losses of water from the test solution resulting from evaporation.

#### 2.34.3.3 Water-Line Tests

Materials may be subject to intense localized attack at the liquid level when they are partially immersed in a solution under conditions where the water line remains at a fixed position for long periods. This attack may be the result of concentration cell effects complicated by differences in the nature and adherence of corrosion-product films as they form in the water-line region as compared with those that form above or below this region.

The testing technique is very simple since it involves no more than providing means of supporting a specimen or specimens in a fixed position of partial immersion, and of maintaining the liquid level constant by the continuous addition of distilled water to

make up for evaporation losses. For maximum reproducibility of results, the dimensions of the specimens, and especially the ratio of areas above and below the liquid level, should be held constant, as should be the depth of immersion.

#### 2.34.3.4 Heat-Flux Effects

When heat flows into or out of a fluid through a containing wall, the wall surface reaches a temperature that differs from that of the bulk of the fluid. The wall's corrosion resistance at this temperature may be significantly different from its resistance at the bulk-fluid temperature. Tubes or tank walls heated by steam or direct flame have failed in service in which similar materials, not so heated, performed acceptably.

The name 'hot wall effect' was given to this phenomenon by Benedicks<sup>48</sup> who observed separation of dissolved gas from aerated water in boiler tubes. The metal wall was insulated from the cooler boiler water by the gas, its temperature rose substantially, and the more severe corrosion took the form of pitting. It was recognized subsequently that even without such gas formation, a hot-wall effect resulted when heat flowed through a wall into a fluid. The temperature difference that had to exist in order for heat to flow was increased by the insulating effect of the thin film of almost stagnant fluid at the wall surface. This film is thinned by rapid flow of a fluid through a tube, but is not eliminated at any finite velocity. Boiling of a liquid, by either bubble nucleation or coverage of the heating surface by a vapor film, increases the skin temperature further; the second mechanism provides much more severe insulation and greater temperature rise.<sup>49</sup>

High rates of heat flow through heat-transfer surfaces in atomic energy installations studied by Groves made him develop an appropriate corrosion test method.<sup>50</sup> In this, a small sheet specimen in contact with a hot liquid, usually boiling, is heated externally so that its surface reaches the desired test temperature. The surface or skin temperature is close to the temperature at mid-thickness, which is measured by a thermocouple inserted in a drilled hole. The heating source is an electric soldering iron in which the tip is replaced by a flat-surfaced metal block. The voltage to the heat source is controlled by a variable transformer. Supplementary heating may be provided to the liquid in the test vessel by winding the liquid container with resistance wire, or by an immersion heater (Figure 6).

A similar unit, modified in details such as location of condenser, use of an agitator, and shape of the

**Figure 6** Device for studying hot wall effects.

vessel, was used by Fisher and Whitney.<sup>51</sup> Further substantial modifications to permit interface location of specimens, cooling of specimens and operation under applied pressure, have been described by Fisher.<sup>52</sup> Earlier laboratory test methods tried by Fisher and Whitney<sup>51</sup> included exposure of specimens heated by their own electrical resistance and of tubular specimens containing a pencil-type resistance-wire heater in a quartz tube.

To investigate corrosion in heated crevices filled with wetted paste a sandwich test assembly was designed by Gleekman and Swandby<sup>347</sup> simulating a slotted cylindrical steam-heated drier. Two plates are bolted together, the lower being heated by an electric hot plate.

It has been concluded from data reported in these studies that the skin temperature is the major controlling factor in corrosion, not the rate of heat flow through the metal.<sup>51</sup> It has also been concluded, however, that corrosion rates at a given mid-specimen temperature do depend on the presence or absence of thermal flux.<sup>53</sup> The difference between temperatures at skin and mid-specimen positions may account for this discrepancy.

Heat-flux corrosion rates can also be determined in plant tests using steam-heated tubular specimens which are weighed or callipered.

In addition to the direct effect of film temperature on corrosion rate, an indirect effect has been observed in the heating of some foods and chemicals, in which insulating solid corrosion films on different metals. By raising the metal surface temperature, these films may, when pervious, lead to further corrosion.

Apparatus and procedures for testing the corrosion resistance of alloys in brines at temperatures up to 120–150 °C are described by Hart.<sup>54</sup>

Testing procedures for corrosion inhibitors in heat flux conditions are discussed later.

### 2.34.3.5 Composition of Testing Solution

Changes in corrosivity with time may be observed by exposing fresh specimens to a solution that has already been used for testing. Where such changes are known to occur, or are suspected, it will be necessary to arrange for replacement of the testing solution after appropriate intervals or replenishment of constituents that may be consumed in the corrosion processes.

## 2.34.4 Electrochemical Measurements (General)

In view of the electrochemical nature of corrosion it is not surprising that measurements of the electrical properties of the interface metal–solution (electric double layer) are used extensively in fundamental studies of the mechanism of corrosion, in corrosion testing and in monitoring the control in service. In the context of this section, electrical measurements in the laboratory are used to assess the corrosion behavior of metals and alloys in service and to avoid the more tedious and prolonged field testing. Determinations of the corrosion rate, susceptibility of a metal to bimetallic corrosion, pitting, intergranular attack, stress-corrosion cracking, etc. are examples of corrosion phenomena that are studied in the laboratory by means of electrochemical methods in order to anticipate behavior in service.

Progress in this field has been made possible with increase in knowledge of the detailed mechanism of corrosion and by the developments that have taken place in instrumentation. The widespread use of potentiostatic control and the availability of a range of commercial potentiostats have given a tremendous

impetus to electrochemical testing, and have perhaps led to the unfortunate belief that corrosion testing in the laboratory and in the field can be replaced completely by electrochemical measurements in the laboratory under conditions of controlled potential. Indeed, La Que<sup>55</sup> in 1969 was prompted to express concern about the proliferation of publications describing electrochemical techniques for corrosion testing and to advise caution regarding the extrapolation of results obtained in the laboratory with a potentiostat for the performance of metals in service.

Although important contributions in the use of electrical measurements in testing have been made by numerous workers, it is appropriate here to refer to the work of Stern and his coworkers<sup>56,57</sup> who have developed the important concept of linear polarization, which led to a rapid electrochemical method for determining corrosion rates, both in the laboratory and in plant. Pourbaix<sup>58</sup> and his coworkers on the basis of a purely thermodynamic approach to corrosion constructed potential–pH diagrams for the majority of metal–H<sub>2</sub>O systems, and by means of a combined thermodynamic and kinetic approach developed a method of predicting the conditions under which a metal will (a) corrode uniformly, (b) pit, (c) passivate, or (d) remain immune. Laboratory tests for crevice corrosion and pitting, in which electrochemical measurements are used, are discussed later.

### 2.34.4.1 Techniques

Electrochemical methods of testing involve the determination of specific properties of the electrical double layer formed when a metal is placed in contact with a solution, and these can be summarized as follows.

1. The potential difference across the electric double layer  $\Delta\psi$ . This cannot be determined in absolute terms but must be defined with reference to another charged interface, that is, a reference electrode. In the case of a corroding metal, the potential is the corrosion potential which arises from the mutual polarization of the anodic and cathodic reactions constituting the overall corrosion reaction.
2. The reaction rate per unit area, expressed as the current density  $i$ . For a corroding metal the partial anodic and cathodic current densities cannot be determined directly by means of an ammeter unless the anodic and cathodic areas can be separated physically, for example, as in a bimetallic couple. If the metal is polarized a net current  $i_c$

for cathodic polarization, and  $i_a$  for anodic polarization, will be obtained and can be measured by means of an ammeter.

3. The capacitance. The electrical double layer may be regarded as a resistance and capacitance in parallel, and measurements of the electrical impedance by the imposition of an alternating potential of known frequency can provide information on the nature of a surface. Electrochemical impedance spectroscopy is now well established as a powerful technique for investigating electrochemical and corrosion systems.

The most commonly used measurements are as follows:

1. determination of the steady-state corrosion potential  $E_{\text{corr}}$ ;
2. determination of the variation of  $E_{\text{corr}}$  with time;
3. determination of the  $E-i$  relationships during polarization at constant current density (galvanostatic), the potential being the variable;
4. determination of the  $E-i$  relationships during polarization at constant potential (potentiostatic), the current being the variable;
5. determination of the electrochemical impedance under alternating potential conditions as a function of frequency;
6. determination of electrochemical noise: fluctuations of the free potential or fluctuations of the current when a constant potential is maintained.

#### 2.34.4.2 Instruments

The techniques and instruments used may be classified as follows:

1. *Potential measurements*: a reference electrode and a potentiometer or electrometer that require only a small current to give a measurement of e.m.f. and thus minimize polarization of the electrodes.
2. *Current measurements*: milliammeters or the measurements of the  $IR$  drop across a conductor of known resistance.
3. *Galvanostatic polarization*: constant direct current power units, or banks of accumulators or dry cells used in conjunction with a variable resistance.
4. *Potentiostatic polarization*: potentiostats with varying output currents.
5. *Determination of impedance*: dedicated instruments for the measurement of impedance as a function of frequency.

Impedance measurements, originally used in fundamental studies of anodic oxidation, have great power for deriving corrosion rates and information about reaction mechanisms for processes that occur at a corroding surface using readily available instrumentation. Armstrong *et al.*<sup>59</sup> have used impedance measurements for studying the active-passive transition of chromium and Epelboin *et al.*<sup>60</sup> describe its use for determining the instantaneous corrosion rate of a metal. Sathyaharayana<sup>61</sup> has described a method using Faradaic rectification to determine the instantaneous corrosion rate, in which no reference electrode is required; the electrodes consist of the metal under study and a counter electrode of a large area of the same metal. Macdonald<sup>62</sup> in a review of electrochemical impedance spectroscopy has highlighted the enormous advantage it offers over other electrochemical methods of being able to evaluate the validity of the data using the Kramers–Kronig transforms. While the use of impedance techniques is usually restricted to homogenous corrosion situations, applications to localized corrosion have been reported. These included pitting,<sup>63–65</sup> abrasion,<sup>66</sup> other types of corrosion<sup>67–69</sup> and stress-corrosion cracking.<sup>70</sup> The potentiostatic technique has a number of variations and the potential may be increased or decreased incrementally, changed continuously at a predetermined rate (potential sweep) or applied as pulses of very short duration.

The application of a stochastic approach to the study of pitting was pioneered by Sato.<sup>71</sup> Shibata and Takeyama<sup>72</sup> then developed stochastic theory to study the statistical variation of the pitting potential determined by the potential sweep method. Subsequently, Williams and his coworkers<sup>73–75</sup> described how electrochemical noise (current fluctuations in systems under potentiostatic control or potential fluctuations at the corrosion potential) can be analyzed to provide information on the initiation and propagation of pitting corrosion on stainless steels. In a review Gabrielli *et al.*<sup>76</sup> discuss published results for both stable pitting, where statistical counting is the major technique of investigation, and unstable pitting during the pre-pitting stage, where the techniques that can be applied include statistical counting, ensemble averages, and spectral analysis.

#### 2.34.4.3 Electrochemical Cells

Since the single potential of a metal cannot be measured, it is necessary to use a suitable reference

electrode such as the  $\text{Hg}/\text{Hg}_2\text{Cl}_2/\text{KCl}$  electrode or the  $\text{Ag}/\text{AgCl}/\text{KCl}$  electrode, and although potentials are commonly expressed with reference to the standard hydrogen electrode (SHE), the use of this electrode in practice is confined to fundamental studies rather than testing. Details of the preparation of reference electrodes, salt bridges, capillaries, etc. are given in the book by Ives and Janz<sup>77</sup> and elsewhere.<sup>78–81</sup>

Measurements of the corrosion potential of a single metal corroding uniformly do not involve an  $IR$  drop, but similar considerations do not apply when the metal is polarized by an external e.m.f., and under these circumstances the  $IR$  drop must be minimized by using a Luggin capillary placed close to the surface of the electrode. Even so, the  $IR$  drop is not completely eliminated by this method, and a further error is introduced by the capillary shielding the surface from the current flow with a consequent decrease in current density. At high current density this error due to the  $IR$  drop can conceal the Tafel region by distorting the measured overpotentials, a difficulty that can be overcome by determining the resistance of the solution at the capillary tip and by making an appropriate correction for each value of the current density. Alternatively, electronic feedback circuits may be employed for automatic compensation of the  $IR$  drop, and this method is attractive if rapid variations in overpotential are being studied.<sup>82–85</sup> Other methods include using a Piontelli capillary<sup>86,87</sup> or a rearside capillary<sup>88</sup> (Figure 7). However, in testing in electrolyte solutions of low resistivity these errors are normally small, and the conventional Luggin capillary is used in conjunction with a salt bridge and reference electrode.

For polarization studies, the cell must make provision for the metal electrode under study, an auxiliary or counter electrode, and a Luggin capillary. Provision must also be made for introducing a gas such as oxygen-free nitrogen or argon, which serves to remove dissolved oxygen and to prevent its introduction during the test (or to introduce it if required at predetermined partial pressures) and to agitate the solution; additional agitation if required can be obtained by means of a stirrer (electric or magnetic).

Figure 8 shows the design of an all-glass cell, which has been listed as the standard polarization cell in the ASTM Recommended Practice G 5, which makes provision for the essential requirements listed earlier; this cell is typical of those used for fundamental studies and for testing, although details of design may vary.

The metal electrode to be studied must be carefully prepared, attached to an electrical lead and mounted so that a known surface area of one face is

presented to the solution. Several procedures such as mounting in a cold curing epoxy or polyester resin or inserting into a close-fitting holder of PTFE are used. In the case of metal–solution systems that have a

propensity for pitting, care must be taken to avoid a crevice at the interface between metal specimen and the mounting material (discussion of approaches to the solution of this problem is provided elsewhere). In view of the widespread use of the cell shown in **Figure 8** suitable electrode holders, based on the use of a compression gasket of PTFE or a similar inert polymer, have been designed for bulk metal

specimens,<sup>89,90</sup> wires,<sup>91</sup> tubes,<sup>92</sup> sheets and foil,<sup>93</sup> and for high temperature high-pressure assemblies.<sup>94</sup> Examples of methods of mounting specimens to give a defined area of surface are shown in **Figure 9**.<sup>88</sup>

Various types of reference electrodes are available of which the saturated calomel electrode (SCE), the silver–silver chloride electrode and the copper–copper sulphate electrode are the most widely used in corrosion testing and monitoring. It is appropriate, however, to point out here that the saturated calomel electrode (SCE), the silver–silver chloride electrode and the copper–copper sulfate electrode are the most widely used in corrosion testing and monitoring.

To avoid contamination of the solution under study, and to minimize the liquid-junction potential, it is usual to use a salt bridge, but in many cases this can be dispensed with; thus, if corrosion in a chloride-containing solution is being studied a Ag/AgCl electrode immersed directly in the solution could be used; similarly a Pb/PbO<sub>2</sub> electrode could be used for studies of corrosion in H<sub>2</sub>SO<sub>4</sub>.

#### 2.34.4.4 Measurements of the Corrosion Potential

Pourbaix<sup>58</sup> has provided a survey of potential measurements in relation to the thermodynamics and kinetics of corrosion, and an example of how they can be used to assess the pitting propensity of copper in water.

The determination of the corrosion potential of the two metals constituting a bimetallic couple will provide information on which one of the two will be predominantly anodic and will suffer enhanced corrosion when they are coupled. Similarly the effect of microscopic heterogeneities in alloys on corrosion has been investigated by measuring the corrosion potentials of selected small areas of the surface of the metal. Smith and Pingel<sup>95</sup> coated the surface of the metal with a lacquer of ethyl cellulose (deposited from a volatile solvent), allowed it to dry and then perforated selected areas with a microhardness tester using a steel stylus ground to a truncated cone, and Budd and Booth<sup>96</sup> using a similar technique were able to produce punctures in the film down to 35  $\mu\text{m}$  diameter. Microelectrodes for potential measurements were described by Cleary<sup>97</sup> who used a Ag/AgCl/Cl-electrode with capillary tips down to 15  $\mu\text{m}$ ; Cleary also described microglass electrodes of approximately 30  $\mu\text{m}$  diameter for the determination of pH. Doig and Edington<sup>98</sup> used microelectrodes with an internal diameter at the tip of about 0.2  $\mu\text{m}$  to measure localized corrosion potentials in the grain boundary regions of aged Al–Mg and Al–Cu alloys,

and Davis<sup>99</sup> used microelectrodes with a tip diameter of 1  $\mu\text{m}$  to measure pH during stress corrosion of aluminum alloys.

Potential–time relationships have been widely used for studying film formation and film breakdown, as indicated by an increase or decrease in the corrosion potential, respectively. May<sup>100</sup> studied the corrosion of 70/30 brass and aluminum brass in seawater and showed how scratching the surface resulted in a sudden fall in potential to a more negative value followed by a rapid rise due to reformation of the film; conversely, the pitting of stainless steel in chemical plant may be detected by a sudden decrease in potential.<sup>101</sup>

Hoar and his coworkers<sup>102,103</sup> used potential changes to study film breakdown and repair during the stress-corrosion cracking of austenitic stainless steels in boiling saturated  $\text{MgCl}_2$  solution. Horst, *et al.*<sup>104</sup> have used potential measurements as a test to predict, the stress-corrosion susceptibility of 2219 aluminum alloy products (alloys containing approximately 6% Cu and tempered to give maximum strength and resistance to stress-corrosion cracking). The test solution used was methanol plus carbon tetrachloride and, it was shown that susceptible alloys were 200–500 mV more positive than nonsusceptible alloys, and that this difference in potential was revealed in less than 1 h. They claim that the test is more sensitive than that in which sodium chloride plus hydrogen peroxide is used as the test solution, since the latter gives potential differences of only 20 mV.

ASTM G 5 outlines standard methods for making potentiostatic and potentiodynamic anodic polarization measurements and ASTM G 3 gives conventions applicable to electrochemical measurements in corrosion testing. Further information and references are provided elsewhere.

### 2.34.5 Polarization Resistance

It is evident from previous considerations that the corrosion potential  $E_{\text{corr}}$  provides no information on the corrosion rate, and it is also evident that in the case of a corroding metal in which the anodic and cathodic sites are inseparable (cf. bimetallic corrosion) it is not possible to determine  $i_{\text{corr}}$  by means of an ammeter. The conventional method of determining corrosion rates by mass-loss determinations is tedious and over the years attention has been directed to the possibility of using instantaneous electrochemical methods. Thus, based on the Pearson derivation,<sup>105</sup>

Schwerdtfeger, *et al.*<sup>106,107</sup> have examined the logarithmic polarization curves for ‘potential breaks’ that can be used to evaluate the corrosion rate; however, the method has not found general acceptance.

Skold and Larson<sup>108</sup> in studies of the corrosion of steel and cast iron in natural water found that a linear relationship existed between potential and the applied anodic and cathodic current densities, provided the values of the latter were low. However, the recognition of the importance of these observations is due to Stern and his coworkers<sup>56,57</sup> who used the term ‘linear polarization’ to describe the linearity of the  $E$  versus  $i$  curve in the region of  $E_{\text{corr}}$ , the corrosion potential. The slope of this linear curve,  $\Delta E$  versus  $\Delta i$  or  $\Delta E$  versus  $\Delta i$ , is termed the polarization resistance,  $R_p$ , since it has dimensions of ohms, and this term is synonymous with ‘linear polarization’ in describing the ‘Stern–Geary’ technique for evaluating corrosion rates.

Stern and Geary<sup>56,57</sup> on the basis of a detailed analysis of the polarization curves of the anodic and cathodic reactions involved in the corrosion of a metal, and on the assumption that both reactions were charge-transfer controlled (transport overpotential negligible) and that the  $IR$  drop involved in determining the potential was negligible, derived the expression:

$$\frac{1}{R_p} = \left[ \frac{\Delta i}{\Delta E} \right]_{E_{\text{corr}}} = 2.3 \left[ \frac{b_a + |b_c|}{b_a |b_c|} \right] i_{\text{corr}} \quad [1]$$

where  $R_p$  is the polarization resistance determined at potentials close to  $E_{\text{corr}}$ , and  $b_a$ ,  $b_c$  are the Tafel constants; note that in the case of  $b_c$  the negative sign is disregarded. This equation shows that the corrosion rate is inversely proportional to  $R_p$  (or directly proportional to the reciprocal slope of the  $\Delta E$  versus  $\Delta i$  curve) at potentials close to  $E_{\text{corr}}$  (typically within 10 mV), and that  $i_{\text{corr}}$  can be evaluated provided the Tafel constants are known. For a process that is controlled by diffusion of the cathode reactant (transport control) and in which the anodic process is under activation control a similar linear relationship applies:

$$\frac{1}{R_p} = \left[ \frac{\Delta i}{\Delta E} \right]_{E_{\text{corr}}} = \frac{2.3 i_L}{b_a} = \frac{2.3 i_{\text{corr}}}{b_a} \quad [2]$$

where  $i_L$  is the limiting current density of the cathodic reaction and it is assumed that  $i_L = i_{\text{corr}}$

Stern and Weisert<sup>109</sup> by taking arbitrary values of the Tafel constants showed that corrosion rates

determined by the polarization resistance techniques are in good agreement with corrosion rates obtained by mass loss methods.

The importance of the method in corrosion testing and research has stimulated other work, and since the appearance of Stern's papers there have been a number of publications many of which question the validity of the concept of linear polarization. The derivation of linearity polarization is based on an approximation involving the difference of two exponential terms, and a number of papers that have attempted to define the range of validity of polarization resistance measurements have appeared. Barnatt<sup>110,111</sup> derived an analytical expression for the deviations from linearity and concluded that it varied widely between different systems. Leroy,<sup>112</sup> using mathematical and graphical methods, concluded that linearity was sufficient for the technique to be valid in many practical corrosion systems. Most authors emphasize the importance of making polarization resistance measurements at both positive and negative overpotentials.

Oldham and Mansfeld<sup>113</sup> approached the problem of linearity in a different way and their derivation avoids the approximation used by Stern and Geary. They conclude that although linearity is frequently achieved, this is due to three possible causes: (a) ohmic control due to the  $IR$  drop rather than control according to linear polarization, (b) the similarity of the values of  $b_a$  and  $b_c$ , and (c) a predisposition by the experimenter to assume that the  $\Delta E$  versus  $\Delta i$  curves near  $E_{\text{corr}}$  must be linear. In a later paper Oldham and Mansfeld<sup>114</sup> showed that linearity of the  $\Delta E$  versus  $\Delta i$  curve is not essential and that  $i_{\text{corr}}$  can be evaluated from the slopes of the tangents of the nonlinear curve determined at potentials of about 20–30 mV more positive and negative than  $E_{\text{corr}}$ .

Hickling,<sup>115</sup> in attempting to study the corrosion of steels under thin film conditions that simulate atmospheric exposure, took into account the time-dependence of polarization measurements, and developed a technique using galvanostatic transients.

### 2.34.5.1 Tafel Constants

It is evident from eqns [1] and [2] that the evaluation of  $i_{\text{corr}}$  from  $R_p$  determinations requires a knowledge of the Tafel constants  $b_a$  and  $b_c$ , which may not be available for the system under study and which may change in value during the progress of the determination. The determination of the Tafel constants from complete  $E$  versus  $i$  curves for each system

studied is time consuming, and may not be particularly accurate owing to resistance and mass transfer effects. Hoar<sup>116</sup> has criticized the method on these grounds and has pointed out that the complete Tafel equations for the anodic and cathodic reactions, which have to be determined to evaluate the Tafel slopes, can be used to calculate  $i_{\text{corr}}$  without resorting to the polarization resistance technique. Mansfeld<sup>117–120</sup> suggests that polarization curves obtained in the  $R_p$  region can be fitted to various theoretical curves, preferably by computer analysis, to give the separate value of both  $b_a$  and  $b_c$ , which since they are determined simultaneously with the  $R_p$  values avoids the criticism that they may change substantially during the corrosion test. (An alternative approach uses the distortion of a small amplitude sine wave as a means of estimating the Tafel constants.)

The controversy that arises owing to the uncertainty of the exact values of  $b_a$  and  $b_c$  and their variation with environmental conditions, partial control of the anodic reaction by transport, etc. may be avoided by substituting an empirical constant for  $(b_a + |b_c| / b_a |b_c|)$  in eqn [1], which is evaluated by the conventional mass-loss method. This approach has been used by Makrides<sup>121</sup> who monitors the polarization resistance continuously, and then uses a single mass-loss determination at the end of the test to obtain the constant. Once the constant has been determined it can be used throughout the tests, providing that there is no significant change in the nature of the solution that would lead to markedly different values of the Tafel constants.

### 2.34.5.2 Applications

The method, in spite of its limitations, has a number of significant advantages and provides a method of rapidly monitoring the instantaneous corrosion rates; furthermore, it has the advantage of the small changes in potential required in the determination not disturbing the system significantly. It is capable of measuring both high and low corrosion rates with accuracy, and may be used as a laboratory tool for testing or research, or for monitoring corrosion rates of plant.

Stern<sup>57</sup> pointed out that the polarization resistance method could be of value for determining the effect of the changes of environment (composition, temperature, velocity) and alloy composition on the corrosion rate and for evaluating inhibitors, and since his original publications the method has been widely used for a variety of studies. Thus, Legault and Walker<sup>122</sup> used the method for studying the

inhibition of the corrosion of steel in chloride solutions by  $\text{NaNO}_2$ , and Walker and France<sup>123</sup> extended this approach to a study of the in situ corrosion of the various metals in automotive-engine cooling systems. Jones and Greene<sup>124</sup> developed the theory of transient linear polarization to study very low corrosion rates, such as those that occur with surgical implant materials, and have shown how polarization resistance data can be used to monitor the onset of pitting or other forms of localized corrosion.

Wilde<sup>125</sup> has applied the Jones d.c.-bridge technique<sup>126</sup> to compensate for errors due to the  $IR$  drop, and has obtained meaningful corrosion rates from polarization resistance data in high temperature high-purity water in nuclear reactors.

Bureau<sup>127</sup> and others<sup>128</sup> have tried to apply the technique for evaluating the corrosion rate of painted metals, and although the results are controversial, the method has also been used successfully in the study of canning materials and lacquered surfaces.<sup>129–131</sup>

Rowlands and Bentley<sup>132</sup> have provided an account of the possibilities for continuously monitoring corrosion rates by polarization resistance measurements, and they also describe the development of a commercial instrument, which uses low-frequency square-wave current to polarize the test specimens.

### 2.34.5.3 Derivation of Linear Polarization Method for Determining Corrosion Rates

It is assumed that

1. The corrosion current  $i_{\text{corr}}$  (it is also assumed that the area of the metal is  $1 \text{ cm}^2$  so that  $I_{\text{corr}} = i_{\text{corr}}$ ) occurs at a value within the Tafel region for the anodic and cathodic reaction, that is, transport overpotential is negligible.
2.  $E_{\text{corr}}$  is remote from the reversible potentials of the anodic and cathodic reactions.
3. The  $IR$  drop in measuring the polarized potential is negligible.

Following Oldham and Mansfeld,<sup>113</sup> but using the symbols that have been adopted in the present work, it is required to show that

$$\left(\frac{di}{dE}\right)_{E_{\text{corr}}} = Z = i_{\text{corr}} \left[ \frac{1}{\beta_a} + \frac{1}{\beta_c} \right] \quad [3]$$

where  $\beta_a$ ,  $\beta_c$  are the Tafel slopes of anodic and cathodic reactions constituting the overall corrosion reaction, that is,  $i_{\text{corr}}$  is linearly related to the polarization resistance ( $dE/di$ ) at potentials close to  $E_{\text{corr}}$ .

(Note that  $\beta$  is used to represent the Tafel slope expressed in terms of natural logarithms, so  $b = 2.3\beta$ .)

At any potential  $E$  the net current is given by

$$i = \bar{i}_1 - |\vec{i}_1| + \bar{i}_2 - |\vec{i}_2| \quad [4]$$

where  $\bar{i}_1$  is the anodic current for metal dissolution and  $\vec{i}_1$  is the reverse cathodic current, and  $\bar{i}_2$  is the cathodic current for the reduction of the cathode reactant (dissolved  $\text{O}_2$ ,  $\text{H}^+$ ,  $\text{H}_2\text{O}$ , etc.) and  $\vec{i}_2$  the reverse current.

The rate of the anodic reaction at a potential  $E$  is given by

$$\bar{i}_1 = i_{0,1} \exp\left(\frac{E - E_{r,1}}{\beta_a}\right) \quad [5]$$

where  $E_{r,1}$  is the reversible potential for the anodic dissolution reaction,  $\beta_a$  is the Tafel slope and  $i_{0,1}$  is the exchange current density. Similarly for the cathodic reaction

$$\vec{i}_2 = i_{0,2} \exp\left(\frac{E_{r,2} - E}{\beta_c}\right) \quad [6]$$

Similar expressions may be written for the partial reverse rates  $\vec{i}_1$  and  $\bar{i}_2$ , but under the conditions assumed here they may be neglected. Hence, substituting eqns [5] and [6] in eqn [4]:

$$i = i_{0,1} \exp\left(\frac{E - E_{r,1}}{\beta_a}\right) - i_{0,2} \exp\left(\frac{E_{r,2} - E}{\beta_c}\right) \quad [7]$$

At the corrosion potential  $E_{\text{corr}}$  the net current  $i$  becomes zero, since  $\bar{i}_1 = |\vec{i}_2|$ . Thus, the two terms on the right-hand side of eqn [7] become equal to one another and equal to  $i_{\text{corr}}$ , the corrosion current density. Thus, replacing  $E$  in eqn [7] by  $E_{\text{corr}}$  gives

$$i = i_{0,1} \exp\left(\frac{E_{\text{corr}} - E_{r,1}}{\beta_a}\right) - i_{0,2} \exp\left(\frac{E_{r,2} - E_{\text{corr}}}{\beta_c}\right) \quad [8]$$

Differentiating eqn [7] with respect to  $E$  gives

$$\frac{di}{dE} = \frac{i_{0,1}}{\beta_a} \exp\left(\frac{E - E_{r,1}}{\beta_a}\right) + \frac{i_{0,2}}{\beta_c} \exp\left(\frac{E_{r,2} - E}{\beta_c}\right) \quad [9]$$

which for  $E = E_{\text{corr}}$  becomes

$$\begin{aligned} \left(\frac{di}{dE}\right)_{E_{\text{corr}}} &= \frac{i_{0,1}}{\beta_a} \exp\left(\frac{E_{\text{corr}} - E_{r,1}}{\beta_a}\right) \\ &+ \frac{i_{0,2}}{\beta_c} \exp\left(\frac{E_{r,2} - E_{\text{corr}}}{\beta_c}\right) \end{aligned} \quad [10]$$

Combining eqns [8] and [10] gives eqn [3] the Stern–Geary equation by simple algebra. However, Oldham and Mansfield point out that further differentiation of eqn [9] gives

$$\frac{d^2 i}{dE^2} = \frac{i_{0,1}}{\beta_a^2} \exp\left(\frac{E - E_{r,1}}{\beta_a}\right) - \frac{i_{0,2}}{\beta_c^2} \exp\left(\frac{E_{r,2} - E}{\beta_c}\right) \quad [11]$$

an equation that demonstrates that there is only one point (a point of inflection, corresponding to a minimum slope) at which the  $i$ – $E$  curve has no curvature and is linear. It follows that

$$\left(\frac{d^2 i}{dE^2}\right)_{E_{\text{corr}}} = \frac{i_{0,1}}{\beta_a^2} \exp\left(\frac{E_{\text{corr}} - E_{r,1}}{\beta_a}\right) - \frac{i_{0,2}}{\beta_c^2} \exp\left(\frac{E_{r,2} - E_{\text{corr}}}{\beta_c}\right) \quad [12]$$

and combining this equation with eqn [8] gives

$$\left(\frac{d^2 i}{dE^2}\right)_{E_{\text{corr}}} = i_{\text{corr}} \left( \frac{1}{\beta_a^2} - \frac{1}{\beta_c^2} \right) \quad [13]$$

For the  $E$  versus  $i$  plot to be linear at  $E \approx E_{\text{corr}}$  ( $d^2 i/dE^2$ ) <sub>$E_{\text{corr}}$</sub>  must be zero, but eqn [13] shows that this will be true only if  $\beta_a = \beta_c$ . (Note that this does not invalidate the basic Stern–Geary equation, it merely shows that the  $d^2 E/di^2$  is only zero at  $E_{\text{corr}}$  if  $\beta_a = \beta_c$ , so that it could be argued that the use of the word ‘linear’ is not strictly accurate.)

#### 2.34.5.4 Simultaneous Determination of Tafel Slopes and Corrosion Rates from $R_p$ Determinations

Mansfield<sup>120</sup> points out that a major limitation of the polarization resistance is that the factor  $b_a b_c / 2.3(b_a + b_c)$  must be determined in order to evaluate  $I_{\text{corr}}$  and has devised a procedure in which this can be achieved by a graphical method.

The Stern–Geary equation can be written in the form

$$I_{\text{corr}} = \frac{b_a b_c}{2.3(b_a + b_c)} \times \frac{1}{R_p} = \frac{B}{R_p} \quad [14]$$

where  $B = b_a b_c / 2.3(b_a + b_c)$  and  $R_p = (dE/dI)$  at  $E_{\text{corr}}$ . Equation [14] is valid only if the relationship between  $I$  and  $E$  can be expressed as

$$I = I_{\text{corr}} \left\{ \exp\left(\frac{2.3(E - E_{\text{corr}})}{b_a}\right) - \exp\left(\frac{-2.3(E - E_{\text{corr}})}{b_c}\right) \right\} \quad [15]$$

Combining eqns [14] and [15] and rearranging gives

$$2.3 R_p I = \frac{b_a b_c}{b_a + b_c} \left\{ \exp\left(\frac{2.3 \Delta E}{b_a}\right) - \exp\left(-\frac{2.3 \Delta E}{b_c}\right) \right\} \quad [16]$$

where  $\Delta E = E - E_{\text{corr}}$ . Since the right-hand side of eqn [16] depends only upon the Tafel slopes it should be possible to evaluate  $b_a$  and  $b_c$  from plots of  $R_p I$  versus  $\Delta E$ .

Figure 10(a) shows a theoretical plot of the right-hand side of eqn [16] versus  $\Delta E$  in which the cathodic

(a)

(b)

**Figure 10** Plots of right-hand side of equation 16 versus  $\Delta E = E - E_{\text{corr}}$  for various combinations of Tafel slopes. (a)  $b_c$  constant at 120 mV,  $b_a$  varied and (b)  $b_a = b_c = b$ . Reproduced from Mansfield, F. J. *Electrochem. Soc.* **1973**, 120, 515.

Tafel slope has been assumed to be constant at 120 mV and the anodic Tafel slope to have the arbitrary slopes of 40, 60, and 120 mV. It can be seen that linearity over a range of positive and negative potentials  $\Delta E$  is achieved only when  $b_a = b_c$  and that linearity is confined to  $\Delta E \approx 0$  when  $b_a$  and  $b_c$  differ.

In **Figure 10(b)** it has been assumed that the Tafel slopes are equal, that is,  $b_a = b_c = b$  and the modified expression for the right-hand side of eqn [16] has been plotted against  $\Delta E$  for different values of  $b$  (e.g., 30, 60, and 120 mV). Comparison of **Figure 10(a)** and **10(b)** shows how the curvature of the plots differs at cathodic potentials, that is,  $\Delta E < 0$ . Thus, the kinetic behavior of a corroding metal, as expressed by different combinations of Tafel slopes, can be organized by this method of plotting curves. This theoretical approach has been confirmed experimentally by Mansfeld for the system Fe/H<sub>2</sub>SO<sub>4</sub>.

Mansfeld points out that  $I_{\text{corr}}$  can be calculated from the measured polarization curve by the following four steps, which are based on eqns [14] and [15]. (With the advent of low cost computing power, and computerized systems for the acquisition of polarization data, this process can be automated by fitting eqn [8] (or rather a simplified form of this equation, taking account of the fact that  $i_{0,1}$  and  $E_{r,1}$  (and  $i_{0,2}$  and  $E_{r,2}$ ) can be replaced by any current–potential pair that lies on the Tafel line, one such pair being  $i_{\text{corr}}$  and  $E_{\text{corr}}$  for both anodic and cathodic reactions), or a more sophisticated model of the  $E$ – $i$  relationship, to the measured data by adjusting the variable parameters (for a recent example see Guinea, D. M.; Moreno, B.; Chinarro, E.; Guinea, D.; Jurado, J. R. *Int. J. Hydrogen Energy* **2008**, 33(11), 2774–2782). Alternatively the harmonic analysis and electrochemical frequency modulation methods provide other approaches to obtain this information.)

1. Determine  $R_p$  from:

$$\left[ \frac{\partial I}{\partial E} \right]_{E_{\text{corr}}} = \frac{1}{R_p}$$

by drawing a tangent at  $\Delta E = 0$  that is, at  $E_{\text{corr}}$ .

2. Multiply the current  $I$  measured at a certain value of  $\Delta E$  by  $2.3 R_p$  and plot  $2.3 R_p I$  versus  $\Delta E$  for various values.
3. Determine from this plot the Tafel slopes  $b_a$  and  $b_c$  by curve fitting using the theoretical curves calculated for various values of  $b_a$  and  $b_c$ .
4. Calculate  $I_{\text{corr}}$  from eqn [14] using the  $R_p$  value evaluated in Step 1 and the Tafel slopes determined in Step 3.

## 2.34.6 Tests for Bimetallic Corrosion

The extent of galvanic effects will be influenced by, in addition to the usual factors that affect corrosion of a single metal, the potential relationships of the metals involved, their polarization characteristics, the relative areas of anode and cathode, and the internal and external resistances in the galvanic circuit.

The results of a galvanic corrosion test on a small scale are as a general rule no more than semiquantitative. A principal reason for this is that the magnitude of the galvanic effect is a function of galvanic current density which is usually determined by the relative areas of the metals forming the couple. There may also be major differences in circuit resistances in tests as compared with practice – especially if current-measuring shunts of substantial resistance are made part of the circuit in the test. The geometric relationship between the metals in the test will also influence the result through effects on electrolyte resistance and the distribution of the galvanic currents.

The simplest procedure in studying galvanic corrosion is a measurement of the open-circuit potential difference between the metals in a couple in the environment under consideration. This will at least indicate the probable direction of any galvanic effect, although no information is provided on the rate. A better procedure is to make similar open-circuit potential measurements between the individual metals and some appropriate reference electrode, which will yield the same information and will also permit observations of any changes in the potential of the individual metals with time that will affect the overall potential difference in the couple. For most practical laboratory testing, the saturated calomel half cell is most convenient. The precision of the determinations is adequate and it is easy to maintain a constant concentration of potassium chloride.

The preferred potential-measuring instruments are high-input impedance voltmeters that permit measurements to be made without flow of sufficient current to polarize the electrodes during the determinations.

Open-circuit potential measurements do not indicate the all important effects of continued current flow, and much more information is derived from frequent or continuous determinations of the magnitude of the galvanic current. In making these measurements it is necessary to avoid the use of instruments that will introduce sufficient resistance to exert a controlling effect on the magnitude of the galvanic current being measured. Instruments (zero-resistance ammeters) that permit current measurements to be made with

zero resistance in the measuring circuit (see Ailor)<sup>2</sup> are available.

In less critical cases it will suffice to include in the circuit a low value resistance over which  $IR$ -drop potential measurements can be made for calculation of the current. This technique permits measurements to be made as required without opening the circuit even momentarily for the introduction of current-measuring devices.

An obvious method for studying galvanic corrosion either with or without supplementary electrical measurements is to compare the extent of corrosion of coupled and uncoupled specimens exposed under identical conditions. Such measurements may use the same techniques for estimating corrosion damage, such as mass-loss determinations, as have been described in connection with ordinary corrosion tests.

A convenient method of carrying out such a galvanic test in the laboratory has been described by Wesley<sup>133</sup> in which the vertical circular-path machine is used. Each assembly includes two pairs of dissimilar metals – one pair coupled galvanically while the other pair is left uncoupled to determine the normal corrosion rates under the same environmental conditions. The type of motion provided (specimens moving in a vertical circular path) enables electrical connections to be made without mercury cup or commutator and the leads can be connected to a calibrated resistance for current measurements attached to the specimen carrier.

It is often of interest also to measure both the external and internal resistances of the galvanic circuit by the use of appropriate resistance-measurement bridges or by even more elaborate techniques such as those described by Pearson.<sup>105</sup>

It is often desirable to know something about the probable distribution of galvanic effects in a galvanic couple. This will be determined, of course, by the size and shape of the different metals and how they are placed relative to each other – whether more or less parallel in the electrolyte, close together or far apart, or joined along some line of contact. The distribution from such a line of contact may be observed directly if the test couples are exposed in this way and for long enough for sufficient corrosion to occur for it to be observed and measured. Alternatively, the distribution of the galvanic currents in terms of the current density on different portions of both the anode and cathode surfaces may be estimated from data derived from surveys of the potential field in the electrolyte around the couple. Such a potential survey may be made using a fixed and a movable reference electrode so that equipotential lines in several planes may be measured

and plotted as was done by Copson<sup>134</sup> using a technique originally proposed by Hoar. By analysing the data from the potential surveys, it is possible to calculate the current distribution over different areas near and remote from the contact of the dissimilar metals. This technique has been used by Rowe<sup>135</sup> to study the corrosion behavior of coated and uncoated couples.

Guidance on conducting and evaluating galvanic corrosion tests in electrolytes is given in ASTM G 71.

## 2.34.7 Soil Tests

Soil corrosion does not lend itself readily to direct study in the laboratory. However, indirect methods involving the action of differential aeration cells have yielded valuable information in comparing the probable corrosivities of different soils towards steel. The details of this technique were described by Denison,<sup>136</sup> Ewing,<sup>137</sup> Schwerdtfeger,<sup>138–141</sup> and by Logan *et al.*<sup>142</sup>

The Schwerdtfeger<sup>138–141</sup> ‘polarization break’ and the polarization resistance methods have been studied by Jones and Lowe<sup>143</sup> in relation to their effectiveness in evaluating corrosion rates of buried metals. A Holler bridge circuit was used to remove  $IR$  contributions during the measurement of the polarized potential. Jones and Lowe, on the basis of their studies of buried steel and aluminum specimens, concluded that the polarization resistance was the most useful, and that the polarization break had the serious limitation difficult to making it identify the breaks in the curve.

## 2.34.8 Accelerated Tests – Electrolytic Tests

In view of the electrochemical nature of corrosion, it has seemed reasonable to many investigators to assume that suitable accelerated corrosion tests could be made by observing the response to electrolytic stimulation of the corrosion processes, or by attaching particular significance to the results of quickly made electrode potential and current measurements.

Acceleration of corrosion by electrolytic stimulation has sometimes been found to distort normal corrosion reactions to such an extent that the results bear no consistent relationship to ordinary corrosion and are, therefore, quite inconsistent and unreliable. This was shown, for example, by a series of tests sponsored by ASTM Committee B-3.<sup>144,145</sup> Nevertheless, considerable success has been achieved with the development

of the electrochemical potentiokinetic reactivation (EPR) test as an accelerated method for the detection of sensitization in austenitic stainless steels. This is discussed subsequently in the section concerned with intergranular attack of Cr–Ni–Fe alloys.

Measurements of open-circuit potentials relative to a reference electrode have been assumed on occasion to provide a means of rating metals as to their relative resistance to corrosion on the basis that the more negative the measured potential, the higher will be the rate of corrosion, but this assumption is obviously invalid, since it disregards polarization of the anodic and cathodic areas. (More importantly, it ignores the possibility of passivation, which leads to a more positive potential, but a reduced corrosion rate compared to active corrosion.)

Some examples of the use of potential measurements in corrosion tests have been given and it is of interest to outline here certain test procedures that are used industrially to supplement or replace the more tedious and prolonged laboratory and field tests. These tests frequently rely on changing the potential as a means of accelerating the test, and although, as emphasized earlier, this is capable of distorting the mechanism, it is less likely to do so than a change in the nature of the environment, an increase of temperature, etc. The majority of these tests are used for evaluating electrodeposits, anodized coatings, and paint films.

#### 2.34.8.1 Electrolytic Oxalic Acid Etching Test

This test has been developed and used by Streicher<sup>146–149</sup> as a screening test to be used in conjunction with the tedious boiling nitric acid test for assessing the susceptibility of stainless steels to intergranular attack as specified in ASTM A 262, and will be considered subsequently in the section concerned with intergranular attack of Cr–Ni–Fe alloys.

#### 2.34.8.2 The Electrolytic Corrosion (EC) Test

The EC test was developed by Saur and Basco<sup>150–153</sup> for decorative Cu (optional) + Ni + Cr electrodeposits. After an appropriate area is masked off and cleaned with a slurry of MgO, the specimen is immersed in test solution A or B (Table 2). It is held by means of a potentiostat at +0.3 V (versus SCE) and taken through cycles of 1 min anodically polarized, 2 min unpolarized.

The extent of pitting is estimated by a special microscopic technique, or by the attack on the

**Table 2** Electrolytic corrosion test: composition of test solutions (A, B) and indicators (C, D)

	Concentration			
	A	B	C	D
NaNO <sub>3</sub> (g l <sup>-1</sup> )	10	10		
NaCl (g l <sup>-1</sup> )	1.3	1.0		
HNO <sub>3</sub> (conc.; g l <sup>-1</sup> )	5	5		
1,10-Phenanthroline hydrochloride (g l <sup>-1</sup> )		1.0		
KCNS			3	3
Acetic acid (glacial, ml l <sup>-1</sup> )			2	2

substrate using an appropriate indicator. Thus, in the case of steel 1,10-phenanthroline hydrochloride is added to the electrolyte (solution B) to detect the formation of Fe<sup>2+</sup> ions. Alternatively, the specimens can be removed from the corrosion test solution and placed in an indicator solution, that is, solution C for zinc-base die castings and solution D for steels.

The test is much faster than the CASS test and is probably more reproducible; more important is the fact that it has been correlated with service exposure.

#### 2.34.8.3 Impedance (Aztac) Test

The impedance test<sup>154</sup> for anodized aluminum (ASTM B 457) employs a 1 V r.m.s. 1 kHz source applied to a test cell in an impedance bridge; the electrolyte solution is 3.5% NaCl. The results are expressed as kilohms, and while a bare Al specimen will give a value of about 1 kΩ, a well scaled anodized coating will give a value of 100 kΩ. The admittance test (BS BS EN 12373-5 and BS 3987) is essentially the same as the impedance test but uses 3.5% K<sub>2</sub>SO<sub>4</sub> rather than 3.5% NaCl. An admittance of < 500/*t* μS (where *t* is the thickness of the film in micrometers) denotes good sealing. It should be noted that thickness of the sealed coating should be specified in both tests.

### 2.34.9 Accelerated Tests – Simulated Environments

#### 2.34.9.1 Spray Tests

The most common of the spray tests is the salt-spray or salt-fog test, which was developed originally by

Capp<sup>155</sup> in 1914 for studying the protective values of metallic coatings on steel under conditions that he hoped would simulate exposure to a sea-coast atmosphere. Since then, the test has been used for a number of purposes, for many of which it is not well suited.<sup>156–158</sup>

Although there is no standard size or shape of salt-spray box, certain other features of the test have been standardized in ASTM B 117. Various factors affect the rate of attack and **Figure 11** shows the effect of the angle of exposure of the specimen to the salt droplets, which fall vertically from the spray nozzle, based on early work by May and Alexander.<sup>159</sup> It can be seen that maximum corrosion occurs at angles between about 30° and 80° to the horizontal; vertical exposures were found to give erratic results.

There may be variations from box to box, depending on differences in fog characteristics as influenced by the design of the spray nozzles, the pressure at which the brine enters the nozzle, and the constancy of this pressure.<sup>160</sup>

The results will also be influenced by the concentration of NaCl solution sprayed, some metals are affected more by one concentration than another, for example, zinc is corroded most by a concentrated brine (20%), while iron is corroded most by a dilute brine (3%); synthetic seawater is less corrosive to these metals than either brine. In view of the many other ways by which the conditions within a salt-spray box differ from those of exposure to a natural sea-coast environment, there seems to be no great advantage in making-up complicated synthetic seawaters for use in salt-spray testing. However, tablets for this purpose are commercially available.

Some modified brines have been used in salt-spray boxes for particular purposes, such as the acetic acid-modified brine developed by Nixon<sup>161</sup> to

**Figure 11** Effect of cold-rolled steel specimen position on corrosion in salt-spray test; a is 20% NaCl and b is synthetic seawater.

reproduce the type of blistering frequently encountered on chromium-plated zinc-base die castings. An acetic acid-salt-spray test has been adopted by ASTM (ASTM G 85) and other modifications of the spray test covered by the same standard practice include the cyclic acidified salt spray test, the acidified synthetic seawater spray test and the SO<sub>2</sub> salt spray test. Corresponding tests in the BS series are covered by BS EN 12540. In addition, the original acetic acid-salt-spray test has been modified by including cupric chloride in the brine. This is called the CASS (Copper Accelerated Acetic Acid Salt-Spray) Test; ASTM B 368 test. It is used extensively for testing nickel–chromium coatings on steel and zinc. The original acetic acid-salt-spray test, is modified in an important aspect by the addition of 0.25 g l<sup>-1</sup> of CuCl<sub>2</sub>·2H<sub>2</sub>O, to the 5% NaCl test solution, which substantially increases the corrosivity of the solution, especially to nickel. The addition of FeCl<sub>3</sub> to the acetic acid-salt-spray solution, such as is used in the Corrodokote test, was earlier noted to be troublesome in that it tended to precipitate. For this reason, ferric iron is not included in the CASS test solution. Essential details<sup>162,163</sup> include control of cabinet temperature at 49 °C, control of saturation temperature at 57 °C, control of collection rate at 1.5 ± 0.5 ml h<sup>-1</sup> per 80 cm<sup>2</sup> of specimen surface, control of pH by addition of acetic acid to 3.2 ± 0.1, and an operating air pressure of 103.4 ± 6.9 kN m<sup>-2</sup>. Higher pressure may be required to achieve the specified collection rate in ‘walk-in’ cabinets.

It has been shown that chromium is virtually unattacked by the CASS test solution.<sup>164</sup> Nickel, on the other hand, is corroded at a substantial rate (about 0.072 mm year<sup>-1</sup>), the presence of the copper ions tending to maintain the nickel in an active state.<sup>164,165</sup> Thus, in the CASS test (and in the Corrodokote test as well) accelerated galvanic corrosion of the nickel occurs at any discontinuity in the chromium layer. Good correlation between the results of the CASS test and the performance of plated parts in service has been reported.<sup>164</sup>

#### 2.34.9.2 Corrodokote Test<sup>162,166</sup>

This is a refinement of an earlier test in which melted street slush together with its contained dirt, salts, etc. was splashed upon plated parts by means of a rotating paddle wheel. Parts soiled in this manner were then exposed to a warm, humid atmosphere. The results were striking and significant in that they closely paralleled service experience. The ‘paddle-wheel test’ was

intended to simulate the conditions to which plated parts on automobiles are subjected when cars are garaged, unwashed, after being driven over salted slush-covered city streets on typical winter days. Platings of inadequate thickness and quality have frequently been observed to show signs of failure after only a few weeks' or even a few days' use under such circumstances. Despite certain limitations, good correlation has been reported between the results of the Corrodokote test and service performance of plated components,<sup>133</sup> and it is now included in ASTM B 380 and BS EN 12540 and ISO 4541. Reagents for use in this test are prepared as follows.

1. The cupric nitrate reagent contains 2.5 g  $\text{CuNO}_3 \cdot 3\text{H}_2\text{O}$ , dissolved in 500 ml distilled water.
2. The ferric chloride reagent contains 2.5 g  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ , dissolved in 500 ml distilled water. This reagent should not be kept longer than 2 weeks.
3. The ammonium chloride reagent contains 50 g  $\text{NH}_4\text{Cl}$ , dissolved in 500 ml distilled water.
4. The Corrodokote slurry is prepared by mixing 7 ml of the cupric nitrate reagent, 33 ml of the ferric chloride reagent, and 10 ml of the ammonium chloride reagent with 30 g of kaolin to form a homogeneous slurry, which is sufficient to cover about  $2.79 \text{ m}^2$  of plated surface. A fresh batch of slurry should be made up each day.
5. The surfaces to be tested should be coated with the slurry by brushing in circular motion, finishing with brush strokes in one direction. The coating should then be allowed to dry for 1 h, after which the coated specimen should be put into a noncondensing humidity cabinet at  $38^\circ\text{C}$  and from 90 to 95% RH. After 20 h in the cabinet the specimen should be removed for inspection. Zinc die castings should be cleaned with running water and dried before inspection. Steel specimens should be examined before cleaning and the number of rust spots counted. Since most of the rust will come off with the Corrodokote coating, it may be difficult to distinguish between surface pits and pin holes reaching the basis metal after cleaning. Steel parts may be returned to a condensing humidity cabinet for 24 h or to a salt-spray cabinet for 4 h. Either supplementary exposure will bring out rust spots again.

One cycle of the Corrodokote test will reliably reveal coatings that will not endure one winter's normal use in a typical city that uses salt to deice its streets. In contrast, several cycles of the Corrodokote test are generally required to 'fail' coatings which will withstand one or more such winter's use.

In this connection, there is some indication that while the Corrodokote test can be depended upon to reveal coatings of unsatisfactory durability, there has been some question of its ability to distinguish between, or to predict the relative protective value or length of useful life of different coating systems in the very good or excellent durability range.

Also of questionable significance is the practice of shortening the Corrodokote cycle, to say 4 h, for the purpose of evaluating the durability of relatively thin coatings intended for use under comparatively mild conditions such as indoors or the interiors of automobiles, since by far the greatest amount of corrosion (of the nickel) appears to occur during the early part of the Corrodokote humidity cycle. Good correlation between the Corrodokote test and service performance has been obtained by Bigge.<sup>166</sup>

### 2.34.9.3 Sulfur Dioxide Tests

Historically, two tests in which sulfur dioxide is the principal corroding agent have been used, that is, the BNFMRSA sulfur dioxide test<sup>167,168</sup> and the Kesternich test.<sup>169</sup> These tests were investigated by the American Electroplaters' Society Research Project 15 Committee early in its search for an acceptable accelerated corrosion test. They were soon abandoned, however, largely because the types of corrosion failures developed did not resemble those that occurred in actual service. Furthermore, the extreme corrosivity of the test environment to nickel (some  $8.38 \text{ mm year}^{-1}$ ) appeared to place an undue premium on the integrity of the overlying chromium deposit, which is virtually unattacked in the test. Thus, coatings that were substandard in respect of nickel or copper-nickel thicknesses might easily pass the test provided the chromium topcoat was completely continuous and remained so for the duration of the test. Conversely, coatings of proven merit on the basis of service experience, such as 0.039 mm of semibright plus bright nickel (duplex) with 0.00025 mm of conventional chromium, could be expected to fail in these  $\text{SO}_2$  tests relatively quickly at any discontinuities in the chromium. In this connection, it is well to keep in mind that, even though the chromium may be non-porous initially, it can hardly be expected to remain so in service on an automobile for example, where it is subject to impact from sand, gravel, etc.

The BNFMRSA test was used in Europe for testing Ni + Cr coatings, but since 1970 it has been omitted from revisions of BS 1224. The test was also used to ensure the quality of anodic coatings on aluminum, but in the current British Standard (BS EN 12373) the

acetic acid salt spray test or the copper-accelerated salt spray test are specified for corrosion testing (BS EN ISO 9227). In the United Kingdom, the Kesternich test, which has obtained the status of an ISO Standard (ISO 6988), is only specified for checking the extent of porosity in tin (BS 1872), tin/lead (BS 6137) and tin/nickel (BS 3597) coatings. In the United States, another version with a much more aggressive atmosphere is used to detect porosity in gold coatings on copper, nickel or silver (ASTM B 735) but the equivalent British Standard (BS EN ISO 27874) specifies electrographic tests for this purpose.

Sulfur dioxide is not included as a corrosion test medium in the current ISO Standard for electrodeposited coatings of nickel + chromium and of copper + chromium (ISO 1456). However, one important use of sulfur dioxide atmospheres as a controlled accelerated test has been for electrical (and, particularly, electronic) contacting surfaces. In this case, the concentration of SO<sub>2</sub> is much less than for the Kesternich test and the time of testing is much longer (IEC 60068-2-49).

Because moist air containing sulfur dioxide quickly produces easily visible corrosion on many metals in a form resembling those that occur in industrial environments, ASTM have issued a Standard Practice for conducting tests in moist SO<sub>2</sub> (G 87). This suggests that such tests are well suited to detect pores or other sources of weakness in protective coatings and deficiencies in corrosion resistance associated with unsuitable alloy composition or treatments. However, it is stressed that the results obtained should only be taken as a general guide to the relative corrosion resistance of these materials in moist SO<sub>2</sub> service.

#### 2.34.9.4 General Considerations of Spray and SO<sub>2</sub> Tests

The salt-spray test has seemed to yield the most consistent results when used to establish the relative merits of different aluminum alloys in resisting attack by marine atmospheres. The best results have been secured when the spray has been interrupted for many hours each day.<sup>170</sup>

Salt-spray boxes are also used for studying the deterioration and protective value of organic coatings, although this test is of doubtful value for such purposes, since it fails to include many factors, for example, sunlight, which affects the life of such coatings. Methods of testing organic coatings are discussed elsewhere. The variable responses of different metals and coatings to the conditions that can be set up in salt-spray boxes, as well as to the conditions that

exist in natural atmospheres, make it impossible to determine the equivalent in some natural atmosphere of say an hour in a salt-spray box.

For additional information on some of the features of the salt-spray test and its limitations in respect of certain purposes for which it may be used, reference should be made to the book *Corrosion Testing for Metal Finishing*<sup>171</sup> prepared by the Institute of Metal Finishing.

There have been several attempts to develop rather elaborate testing machines in which specimens may be subjected to various sprays of fogs with cycles of condensation, heating, and drying. The object has been to reproduce the conditions encountered by metals exposed in polluted industrial atmospheres. Such devices have been experimented with in the United Kingdom<sup>172</sup> and the United States.<sup>173</sup> While it is sometimes possible for such tests to rate steels in a rough order of resistance to atmospheric corrosion, it should be appreciated that the nature of rust formed may differ from that obtained during actual exposure. It is only in rare cases that the resistance to attack by the sprays is analogous to their resistance in the natural atmosphere, which the tests seek to simulate. Such parallelism is not common enough to make these tests very reliable.<sup>174</sup>

Dennis and Such<sup>175</sup> point out that the BNFMRASO<sub>2</sub> test was really a means of detecting discontinuities in the chromium layer of a Cr + Ni coating system and it therefore gave unfavorable results when used for testing microcracked or microporous Cr, since the Cr was rapidly undermined, with consequent flaking. Conversely, the test exaggerates the beneficial effect of crack-free Cr. The test also fails to indicate the improved corrosion resistance of duplex Ni when compared with bright Ni. A critical account of laboratory corrosion testing methods for Ni-Cr coatings is given by Dennis and Such.<sup>176</sup>

#### 2.34.9.5 Accelerated Tests for Weathering Steels

Interest in weathering steels has stimulated work on accelerated laboratory tests that can be used to investigate the effect of alloy composition on performance. It is well established that a wetting and drying cycle should be an integral part of any laboratory test in which the characteristic properties of weathering steels are revealed,<sup>177</sup> and Bromley, Kilcullen, and Stanners<sup>178</sup> have designed a test rig (Figure 12) that provides results that can be correlated with actual atmospheric exposure data. The rig has been designed to investigate

**Figure 12** Rig used for laboratory evaluation of weathering steels. (a) General layout showing unimmersed and immersed positions and (b) detailed view of central position of cabinet. Reproduced from Bromley, A. F.; Kilcullen, M. B.; Stanners, J. F. In 5th European Congress of Corrosion, Paris, September 1973.

a wide range of alloying elements in a development program on slow-weathering steels for which it was essential to have a rapid, reliable and reproducible test that incorporated the specific atmospheric factors responsible for rust formation.

The results obtained with this equipment show that the corrosion rate in the rig is about four times that encountered in an industrial UK atmosphere. This acceleration, however, is not achieved by accentuating any of the environmental factors, but rather by holding them near the worst natural conditions for as long as possible. The procedure used ensures that the rust film is completely dried for short periods, thus simulating the conditions that bring out the beneficial effects of protective rust films on the steels under study.

The use of electrochemical tests for rapid assessment of the performance of these steels has attracted interest, and Pourbaix<sup>179</sup> has devised an apparatus in which potential measurements are used to evaluate the protective nature of corrosion products formed on low-alloy steels, such as the weathering steels, during periodic wetting and drying. The apparatus (Figure 13) consists of a glass tank containing an appropriate electrolyte, such as a natural or artificial water. Two specimens of the metal or alloy under study are attached to a spindle that rotates slowly

**Figure 13** Equipment for studying patina formation on low alloy steels. Reproduced from Pourbaix, M. CEBELCOR RT; 1969, 160.

(about  $1 \text{ rev h}^{-1}$ ) so that the specimen is immersed in the solution for approximately half the time and exposed to the atmosphere for the remaining time. An electric lamp is placed above the tank so that the specimens remain wet for a time after withdrawal from the solution, but are completely dried during the cycle. Measurement of the potentials of the specimens at the beginning and end of the immersion period is effected by means of the commutators, which are attached to the spindle but electrically insulated from it, and a reference electrode. The e.m.f. taken from the terminals can be fed to a multipoint recorder so that a recording of the  $E$ -time relationship may be obtained for each specimen. The solution can be made to circulate slowly by allowing it to drip from a feed and overflow via a siphon. In a variation of the apparatus, a Luggin capillary is attached to the sample so that the potentials can be measured during the period when the specimen has emerged from the solution but is still wet.

Figure 14 shows results obtained from the apparatus for different steels some of which (nos. 1, 2, 3, and 7) form a protective patina for corrosion products, while others (nos. 4, 5, and 6) form patinas that are nonprotective; the criterion adopted is that the more positive the potential the more protective is the rust patina.<sup>179</sup>

Legault *et al.*<sup>180,181</sup> have used open-circuit potential versus time measurements and cathodic reduction of rust patinas for the rapid laboratory evaluation of the performance of low-alloy weathering steels. The steel specimens are first exposed for 48 h to the vapor of an  $0.001 \text{ mol dm}^{-3}$  sodium bisulfite solution maintained at  $54^\circ\text{C}$  (humid  $\text{SO}_2$ -containing atmosphere) to stimulate corrosion under atmospheric conditions. They are then subjected to two types of test: (a) open-circuit potential-time tests for periods up to 3000 s in either distilled

**Figure 14** Relationship between potential (determined during initial immersion using the equipment in **Figure 13**) and time for steels that form protective (1, 2, 3, 7) or nonprotective (4, 5, 6) patinas. Reproduced from Pourbaix, M. CEBELCOR RT; 1969, 160.

water or  $0.1 \text{ mol dm}^{-3} \text{ Na}_2\text{SO}_4$  and (b) cathodic reduction in  $0.1 \text{ mol dm}^{-3} \text{ Na}_2\text{SO}_4$  at  $1 \text{ mA cm}^{-2} \text{ c.d.}$  In the cathodic reduction experiments, which provide a means of evaluating the degree of rusting,<sup>182</sup> both the potential and time are recorded, the onset of hydrogen evolution at constant potential being taken as the end point and giving the oxide-reduction time.

In order to evaluate the tests, determinations were carried out on the steels that had been exposed to the atmosphere for 1, 2, 3, 4, and 6-month periods. It was established that the initial open-circuit potential and the decrease in potential (more negative) with time varied with the nature of the steel and the time of exposure to the atmosphere, and the maximum negative potential was taken as a measure of corrosion

resistance; the more negative the potential the lower the resistance of the alloy. In the case of three alloy steels that differed only in copper content it was found that the open-circuit potential was related to the corrosion rate as assessed by conventional weight loss.

A relationship was also established between the oxide-reduction time and time of exposure, and the results for a mild steel and a 1Cu–3Ni weathering steel were similar to those obtained by mass loss. The authors give various expressions that relate oxide-reduction time (min) with corrosion rate ( $\text{mm year}^{-1}$ ), and claim that a short exposure to a laboratory  $\text{SO}_2$  atmosphere followed by determining the  $E$  versus time and oxide-reduction time provides a rapid method of evaluating weathering steels.

### 2.34.10 Intergranular Attack of Cr-Ni-Fe Alloys

Early in the history of stainless steels it was recognized that they were highly susceptible to intergranular attack resulting from the precipitation of Cr-Fe carbides with the consequent depletion in the chromium content at grain boundaries when the alloy was heated in a specific range of temperature. It was necessary, therefore, to develop methods of testing that would detect susceptibility to intergranular attack as influenced by variations in processing and/or composition. As will be seen, most reagents used for these tests are highly aggressive, and it is important to note that an alloy found to be susceptible during testing will not necessarily be attacked intergranularly under the milder environmental conditions that may prevail in service.

Brown<sup>183</sup> has pointed out that Du Pont used evaluation tests for (a) as-received unstabilized alloys containing more than 0.03% C to check the effectiveness of the final heat treatment and (b) stabilized or special low-carbon grades after a sensitizing treatment (1 h at 677°C) to determine whether susceptibility might develop during a subsequent welding operation.

Intergranular corrosion of Fe-Ni-Cr alloys has been the subject of a comprehensive review by Cowan and Tedmon<sup>184</sup> who summarized the various tests used for determining susceptibility (Table 3).

Of these tests, nos. 1-5, which are regarded as reliable test procedures by the ASTM, have been incorporated into ASTM A 262 'Standard Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels' as follows:

Practice A – 10% oxalic acid, electrolytic etching at ambient temperatures;

Practice B – Boiling 50%  $\text{H}_2\text{SO}_4$  + 25 g  $\text{l}^{-1}$   $\text{Fe}_2(\text{SO}_4)_3$ ;

Practice C – Boiling  $\text{HNO}_3$ ;

Practice D – 10%  $\text{HNO}_3$  + 3% HF at 70°C;

Practice E – Boiling 16 wt%  $\text{H}_2\text{SO}_4$  + 5.7%  $\text{CuSO}_4$  + metallic copper.

It should be noted that although ASTM A 262 provides details of test procedures, no information is given on typical corrosion rates or acceptable limits for various heat-treated alloys, which are regarded as outside the province of a specification that describes test procedures. Table 4, taken from a paper by Brown,<sup>183</sup> shows the maximum acceptable evaluation test rates specified by the Du Pont Company for various alloys

tested by the acid ferric sulfate test and by the Huey test. It should be noted that evaluation tests are specified by Du Pont when it is known or suspected that the environmental conditions in service are conducive to intergranular attack of susceptible material.

All the reagents used in Practice B to E have a high redox potential and Cowan and Tedmon<sup>184</sup> have presented schematic  $E$ -log  $i$  curves (Figure 15) showing the range of potentials of the various tests and the relative rates of attack on the matrix (Fe-18Cr-10Ni) and the chromium-depleted alloy at the grains boundaries, which has been assumed for this purpose to have a composition Fe-10Cr-10Ni, in a hot reducing acid. Although this diagram cannot show the effect of alloy composition, nature of test solution, conditions of test, etc. on intergranular attack, it serves to illustrate the electrochemical principles involved in the test procedures, all of which are based on reagents that attack the intergranular sensitized areas at a higher rate than the matrix; this may lead to the dislodgement of whole grains with a consequent high mass loss.

#### 2.34.10.1 Boiling $\text{HNO}_3$ Test

This test, which is commonly referred to as the Huey test, was first described and used by Huey<sup>185</sup> in 1930, and since that time it has had wide application, particularly in the United States. The test consists of exposing the specimens (20–30  $\text{cm}^2$ ) to fresh boiling 65%  $\text{HNO}_3$  (constant boiling mixture) for five successive periods of 48 h each under a reflux condenser. The specimens are cleaned and weighed after each period, and the corrosion rate (as a rate of penetration) is calculated for each period of test and for the average over the five periods; corrosion rates are expressed as millimeter per year. The reason for this procedure is the fact that Cr(VI) ions, produced from the oxidation of  $\text{Cr}^{2+}$  and  $\text{Cr}^{3+}$  by the  $\text{HNO}_3$ , if allowed to accumulate in the  $\text{HNO}_3$  markedly increase its aggressiveness so that severe intergranular attack with grain dislodgement can occur even with solution-annealed steel free from precipitated carbides; hence, the necessity for the periodic changing of the solution and for a minimum ratio of solution volume to area of specimen (at least 20 ml  $\text{HNO}_3/\text{cm}^2$  of stainless steel). Brown<sup>183</sup> points out that during a normal test the Cr(VI) content will not reach a level where an acceleration in rate occurs unless the specimen is in the sensitized condition, and under these circumstances the presence of Cr(VI) is an advantage in discriminating between sensitized and unsensitized material.

**Table 3** Summary of chemical tests used for the determination of susceptibility to intergranular corrosion of iron–nickel–chromium alloys (Data from Cowan and Tedmon)

Test name	Usual solution composition	Test procedure	Quantitative measure	Potential range (V vs. SHE)	Species selectivity attacked
1. Nitric acid test <sup>a</sup>	65 wt% HNO <sub>3</sub>	Five 48-h exposures to boiling solution; refreshed after period	Average mass loss per unit area of five testing periods	+0.99 to +1.20	1. Chromium-depleted areas 2. $\sigma$ -phase 3. Chromium carbide
2. Acid ferric sulfate (Streichet) test <sup>b,c</sup>	50 wt% H <sub>2</sub> SO <sub>4</sub> + 25 g l <sup>-1</sup> ferric sulfate	120 h exposure to boiling solution	Mass loss per unit area	+0.7 to +0.9	1. Chromium-depleted areas 2. $\sigma$ -phase in some alloys
3. Acid copper sulfate test <sup>b,d</sup>	16 wt% H <sub>2</sub> SO <sub>4</sub> + 100 g l <sup>-1</sup> CuSO <sub>4</sub> (+ metallic copper)	72 h exposure to boiling solution	1. Appearance of sample upon bending 2. Electrical resistivity change 3. Change in tensile properties	+0.30 to +0.58	Chromium-depleted area
4. Oxalic acid etch <sup>b</sup>	100 g H <sub>2</sub> C <sub>2</sub> O <sub>4</sub> ·2H <sub>2</sub> O + 900 ml H <sub>2</sub> O	Anodically etched at 1 A/cm <sup>2</sup> for 1.5 min	1. Geometry of attack on polished surface at $\times 250$ or $\times 500$	+1.70 to +2.00 or greater	Various carbides
5. Nitric-hydrofluoric acid test <sup>e</sup>	10% HNO <sub>3</sub> + 3% HF	4 h exposure to 70 °C solution	Comparison of ratio of mass loss of laboratory annealed and as-received samples of same material	Corrosion potential of 304 steel = +0.14 to +0.54	1. Chromium-depleted areas 2. Not for $\sigma$ -phase 3. Used only for Mo-bearing steels
6. Hydrochloric acid test <sup>e</sup>	10% HCl	24 h in boiling solution	1. Appearance of sample after bending around mandril 2. Mass loss per unit area	(a) Redox potential = +0.32 (b) Corrosion potential = $-0.2 \pm 0.1$	1. Alloy-depleted area 2. Not for $\sigma$ -phase
7. Nitric acid Cr <sup>6+</sup> test <sup>f</sup>	5N H <sub>2</sub> SO <sub>4</sub> + 0.5 N KCr <sub>2</sub> O <sub>2</sub>	Boiling with solution renewed every 2–4 h for up to 100 h	1. Mass loss per unit area 2. Electrical resistivity 3. Metaflographic examination	(a) Redox potential = +1.37 (b) Corrosion potential of 304 steel = +1.21	Solute segregation to grain boundaries

<sup>a</sup>Data after Cowan and Tedman.<sup>184</sup><sup>b</sup>A262-02a (2008) and Practice G 28-02 (2008).<sup>c</sup>M. A. Streicher, ASTM Bulletin No. 229, 77–86 (1958) G28-1985.<sup>d</sup>A262-02a (2008).<sup>e</sup>D. Warren, ASTM Bulletin No. 230, 45–56 (1958).<sup>f</sup>J. S. Armijo, *Corrosion*, **24** (1968).

Maximum corrosion rates used by Du Pont for various alloys are given in Table 4, and most users of the test consider average corrosion rates of 0.46–0.61 and 0.76 mm year<sup>-1</sup> to represent the upper limits for satisfactory resistance for wrought austenitic alloys and cast austenitic alloys, respectively. Streicher<sup>148</sup> considers that if the corrosion rate for each period increases over that for the previous period the alloy is susceptible.

The mechanism of the corrosion reaction is not clear, particularly in view of the changes in composition of the HNO<sub>3</sub> that take place during the 48 h period of the test. Streicher<sup>148</sup> reports that the corrosion potential of the steel ranges from 1.00 to 1.20 V (versus SHE) during the test owing to the accumulation of Cr(VI), and it can be seen from Figure 15 that the sensitized areas will have a higher corrosion rate than the matrix throughout this potential range, although they will become similar at the higher potentials. The high corrosion rates obtained in the test are due partly to intergranular attack and partly to the undermining and dislodgement of grains.

Stainless steels and Ni-base alloys containing Mo, such as Type 316L (0.03% C max.) and Hastelloy C, are found to give very high corrosion rates in the HNO<sub>3</sub> test even when they are immune to intergranular attack when subjected to other tests that reveal sensitization due to chromium-depleted zones; furthermore, such alloys even after being subjected to a

sensitizing heat-treatment do not give rise to intergranular attack in most conditions of service. This high corrosion rate is considered to be due to the formation of a submicroscopic  $\sigma$ -phase, and although positive proof is not available, its presence is substantiated by the fact that the phase becomes identifiable after longer periods of sensitizing temperatures, although in this form it has little effect on the corrosion rate. It would appear that the  $\sigma$ -phase dissolves rapidly during the HNO<sub>3</sub> test, and since it has a high chromium content, the solution becomes enriched in Cr(VI) with a consequent increase in the corrosion rate of the alloy. It follows that the test is unsuitable for evaluating the behavior of stainless steels that may precipitate  $\sigma$ -phase, unless the alloy is to be used in service for nitric acid plant.

Henthorne,<sup>186</sup> in considering the corrosion testing of weldments, points out that the test will also give high rates due to (a) end-grain attack, which is particularly prevalent in resulfurized or heavily cold-worked material and (b) dissolution of Ti(C, N) such as occurs in Type 321 weldments and leads to knife-line attack. Since most service conditions do not cause attack on the alloy in these conditions the test can be misleading.

Thus, under the circumstances already outlined, the test can be misleadingly severe, but it is

**Table 4** Maximum acceptable evaluation test rates specified by Du Pont for services where susceptible material would be intergranularly attacked

Type	Condition	Max. corrosion rate (mm year <sup>-1</sup> )
120 h acid Fe <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub> test (ASTM A.262, Practice B)		
304	As received	1.22
304L	20 min at 677 °C	1.22

particularly valuable for evaluating alloys for use in  $\text{HNO}_3$  or in other strongly oxidizing acid solutions to ensure that they have received the correct heat treatment and have an appropriate composition, that is, a low carbon content or the correct ratio of (Ti or Nb)/C.

### 2.34.10.2 Boiling $\text{H}_2\text{SO}_4 + \text{CuSO}_4$ Tests

The use of boiling  $\text{H}_2\text{SO}_4 + \text{CuSO}_4$  for detecting intergranular sensitivity was first described by Strauss, *et al.*<sup>187</sup> in 1930, and is frequently referred to as the Strauss test, although the conditions of the test have been modified; whereas the Huey test is most widely used in the United States the Strauss test has been the preferred test in Europe. The test is mild compared to the Huey test and intergranular attack takes place with little grain dislodgement.

The use of metallic copper chips placed in contact with the steel to speed up the test and thus decrease the time of testing was first described by Rocha,<sup>188</sup> and subsequent work by Streicher<sup>148</sup> showed that its presence significantly increased the rate of intergranular attack even when it was not in contact with the steel. Approximate mass losses for a sensitized Type 316 stainless steel during a 240 h testing in boiling  $\text{H}_2\text{SO}_4 + \text{CuSO}_4$  are as follows:

- No metallic copper present  $0.1 \text{ g dm}^{-2}$ ;
- Metallic copper present but not in contact with the steel  $1.0 \text{ g dm}^{-2}$ ;
- Metallic copper in contact with steel  $4.0 \text{ g dm}^{-2}$ .

As used in Germany the composition of the solution is  $110 \text{ g CuSO}_4 \cdot 5\text{H}_2\text{O}$ ,  $100 \text{ ml H}_2\text{SO}_4$  (spec. grav. 1.84) and  $1 \text{ l}$  of water, the test being conducted for  $168 \text{ h}$  in the boiling solution. The ASTM Tentative Procedure A393–63T specified a similar composition containing  $100 \text{ g CuSO}_4 \cdot 5\text{H}_2\text{O}$ ,  $100 \text{ ml H}_2\text{SO}_4$  (spec. grav. 1.84) with water added to make a total volume of  $1 \text{ l}$ . The test time was  $72 \text{ h}$ , and with the high carbon contents of the earlier steels this was adequate for detecting susceptibility. However, with the decrease in the carbon contents of stainless steels a more prolonged boiling time was found to be necessary, and Scharfstein and Eisenbrown<sup>189</sup> showed that a Type 304 stainless steel containing  $0.068\% \text{ C}$  would pass the  $72\text{-h}$  Strauss test even after a sensitizing treatment of up to  $4 \text{ h}$  at  $677^\circ\text{C}$ . For this reason, A393–63T has been discontinued and in ASTM A 262 Practice E, the specimens are placed in contact with metallic copper chips to increase the rate of intergranular attack.<sup>148,183</sup> This test is of comparable

sensitivity to the other tests, and is far more discriminating than the older tentative standard; furthermore, it is more severe so that the testing time is decreased from  $72$  to  $24 \text{ h}$ . This test has been incorporated in the international standard ISO 3651–2.

Figure 15 shows that the corrosion potential of stainless steel in the  $\text{H}_2\text{SO}_4 + \text{CuSO}_4$  test lies in the range  $0.30\text{--}0.58 \text{ V}$ , and that while the corrosion rate of the unsensitized alloy is approximately  $10^{-1} \mu\text{A cm}^{-2}$ , that of the sensitized material is  $10 \mu\text{A cm}^{-2}$ ; for heavily sensitized material the ratio of rates<sup>184</sup> of sensitized:unsensitized alloy may be as high as  $10^5:1$ . This large difference in rates leads to rapid attack, which is confined to the depleted zone having a thickness of the order of  $1 \mu\text{m}$ , and under these circumstances there will be little grain dislodgement. Thus, the mass change will be so small that it cannot be used as a criterion of susceptibility. For this reason assessment of intergranular attack is normally carried out (ASTM 262 Practice E) by bending the specimen around a mandrel through  $180^\circ$  and inspecting the bend surface for cracks. Measurements of changes in electrical resistivity<sup>146</sup> and in ultimate tensile strength<sup>190</sup> are used as quantitative methods of assessment, but according to Ebling and Scheil<sup>191</sup> they are not as discriminating as the qualitative bend test.

The  $\text{H}_2\text{SO}_4\text{--CuSO}_4$  test, unlike the Huey test, is specific for susceptibility due to chromium depletion and is unaffected by the presence of submicroscopic  $\sigma$ -phase in stainless steels containing molybdenum or carbide stabilizers. It can be used, therefore, with confidence to test susceptibility in austenitic (300 series) and ferritic (400 series) stainless steels and in duplex austenoferritic stainless steels such as Types 329 and 326.

The mechanism of the action of metallic copper was investigated by Streicher<sup>148</sup> who determined the potential of a Type 314 stainless steel, the redox potential of the solution (as indicated by a platinized-Pt electrode) and the potential of the copper. The actual measurements were made with a saturated calomel electrode, but the results reported below are with reference to SHE. In the absence of copper the corrosion potential of the stainless steel was  $0.58 \text{ V}$ , whereas the potential of the Pt electrode was approximately  $0.77 \text{ V}$ . When metallic copper was introduced into the solution (not in contact with the steel) both the corrosion potential of the steel and that of the Pt electrode attained the same high negative potential of  $0.37 \text{ V}$ , the copper attaining a steady value of  $0.30 \text{ V}$ . Finally, when the stainless steel was placed in contact with the copper it took up

a more negative potential of 0.30 V, the potential of the copper being unaffected. These potentials have been interpreted by Streicher and have been expressed in  $E$ - $I$  diagrams (Figure 16) showing how the corrosion potential and the corrosion rate varies with conditions of the test. Introduction of metallic copper into the solution results in the disproportionation reaction:

and the accumulation of the  $\text{Cu}^+$  ions in the solution produces a decrease in the polarization of the local anodes on the stainless steel, which are polarized to the redox potential of the solution (Figure 16). Contact of copper with the stainless steel results in a further decrease in the corrosion potential of the stainless steel to that of copper, indicating that cathodic polarization of the steel has occurred since the steel is the cathode of the stainless steel/copper bimetallic couple. Simultaneously, there is a reduction in the anodic polarization of the susceptible grain boundaries, and a consequent increase in the corrosion rate (Figure 16). Thus, contact of the steel with the copper results in intergranular attack of the steel at constant potential, the copper acting in the same way as a potentiostat.

The Huey test is widely used in the United States while the  $\text{H}_2\text{SO}_4$ - $\text{CuSO}_4$  test is preferred in the United Kingdom, with an increasing tendency to

**Figure 16** Schematic  $E$ - $I$  diagrams of local cell action on stainless steel in  $\text{CuSO}_4 + \text{H}_2\text{SO}_4$  solutions showing the effects of metallic copper on corrosion rate. C and A are the open-circuit potentials of the local cathodic and anodic areas and  $I$  is the corrosion current. The potentials of platinized platinum and copper in the same solution are indicated by arrows. (a) Corrosion of stainless steel in isolation. Soc.* 1959, 106, 161.

use the metallic copper variant. The  $\text{H}_2\text{SO}_4$ - $\text{CuSO}_4$ -Cu test procedure is given in BS EN ISO 3651-2.

### 2.34.10.3 $\text{HNO}_3$ -HF Test

This test was first described by Warren<sup>192</sup> in 1958, and consists of two 2-h periods in 10%  $\text{HNO}_3 + 3\%$  HF solution at 70 °C using fresh solution for each period. The test is therefore more rapid than the others, and it is specific for chromium depletion by carbide precipitation since it is unaffected by the submicroscopic  $\sigma$ -phase formed in molybdenum-bearing steels; as described in A262, its use is confined to Types 316, 316L, 317, and 317L stainless steels.<sup>183</sup> Since the corrosion rates of stainless steels in the acid are high and vary greatly from test to test, it is necessary to run two tests and to compare the corrosion rates of the specimen to be evaluated ('as received' for Types 316 and 317 and in the sensitized condition for Types 316L and 317L) and another laboratory-annealed specimen of the same alloy shown to be free from precipitated carbides by the step structure produced after electrolytic etching in oxalic acid. Intergranular attack is assessed by the rate of penetration evaluated from the mass loss, and if the mass loss of the specimen to be evaluated is greater than 1.5 times that of the standard, the former is considered to be susceptible.

The solution has a low redox potential and the corrosion potentials for austenitic stainless steels will be in the range 0.14–0.54 V, according to composition. Thus, it can be seen from Figure 15 that all but the highest chromium steels will be in the active region, so that the test relies on vigorous corrosion of the grain boundary zones while the matrix remains somewhat passive and corrodes at a slower rate.<sup>184</sup> Although the test gives constant and reliable results, it has not been used widely for routine evaluations for the following reasons: (a) the need to use a ratio of two test rates, (b) inconvenience of handling solution containing HF, and (c) the availability of the  $\text{H}_2\text{SO}_4 + \text{Fe}_2(\text{SO}_4)_3$  test.

### 2.34.10.4 $\text{H}_2\text{SO}_4 + \text{Fe}_2(\text{SO}_4)_3$ Test (Streicher Test)

This was described in 1959 by Streicher,<sup>148</sup> and consists of one period of exposure to a boiling solution of 50 mass%  $\text{H}_2\text{SO}_4 + 25 \text{ g l}^{-1} \text{ Fe}_2(\text{SO}_4)_3$  for 120 h, assessment being based on mass loss (see Table 4). Streicher, however, usually reports a ratio of mass

loss of sample to be assessed/weight loss of annealed sample, and as for the  $\text{HNO}_3$ –HF test considers that a ratio  $>1.5$ – $2.0$  indicates susceptibility; for Type 304 Streicher considers a rate  $>0.76 \text{ mm year}^{-1}$  to indicate susceptibility, but Brown considers a higher figure to be acceptable (see [Table 4](#)).

Accumulation of corrosion products does not stimulate attack and so several specimens may be tested in the same solution, but additional  $\text{Fe}_2(\text{SO}_4)_3$  may have to be added (or the solution changed) if there is considerable attack on severely sensitized specimens, as indicated by a color change of the solution from brown to dark green.

The redox potential of the solution is that of the  $\text{Fe}^{3+}/\text{Fe}^{2+}$  equilibrium and lies within the range  $0.80$ – $0.85 \text{ V}$  (versus SHE). The severe weight loss of susceptible alloys is due to undermining and grain dislodgement at the sensitized zones, which occurs at about twice the rate of that in the Huey test. Another difference is that while in the Huey test corrosion products  $[\text{Cr(VI)}]$  increase the rate by raising the potential of the alloy into the transpassive region, the converse applies in the acid ( $\text{Fe}_2(\text{SO}_4)_3$ ) test, since reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  during the test will result in a decrease in the redox potential and the whole sample will corrode with hydrogen evolution.

According to Cowan and Tedmon<sup>184</sup> the test can selectively attack some types of  $\sigma$ -phase. Those of Types 321 and 347 are readily attacked, whereas the molybdenum-bearing  $\sigma$ -phase of Type 316 is unattacked. The test will also show Hastelloys and Inconels to be susceptible to intergranular attack when there are either chromium- (or molybdenum-) depleted grain boundaries or grain-boundary  $\sigma$ -phase present. Ferritic (200 series) and austenoferritic stainless steels can also be tested for chromium-depletion sensitization in this reagent, but whether  $\sigma$ -phases formed in these alloys affect the test has not been established.

In conclusion it must be emphasized again that all the tests used are accelerated tests and only provide information on susceptibility to intergranular attack under the prevailing precise test conditions. They are quality control tests that may be used to demonstrate either that heat treatment has been carried out adequately or that a steel will withstand the test for a certain sensitizing heat treatment.

#### 2.34.10.5 Electrolytic Oxalic Acid Etching Test

This test, which was developed by Streicher,<sup>148</sup> is used as a preliminary screening test to be used

in conjunction with the more tedious testing procedures such as the boiling  $\text{HNO}_3$  test. The specimens are polished (3/0 grit paper) and then anodically polarized for  $1.5 \text{ min}$  at  $1 \text{ A cm}^{-2}$  at room temperature in a solution prepared by dissolving  $100 \text{ g}$  of  $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  in  $900 \text{ ml}$  of distilled water. The surface is then examined at about  $\times 500$  magnification and the structure is classified as ‘step,’ ‘ditch,’ or ‘dual’ (both ‘step’ and ‘ditch’). If the surface shows a ‘step’ structure it is immune to intergranular attack and no further testing is necessary; if the structure is ‘ditch,’ further testing by the Huey test or some other chemical test is necessary; if ‘dual’ further testing may be necessary. Thus, the test, by identifying structures that are immune to intergranular attack, eliminates unnecessary testing, although where a ‘ditch’ (or possibly a ‘dual’ structure) is obtained, final confirmation by the Huey test is essential. [Figure 17](#) shows the ‘ditch’ and ‘step’ structures diagrammatically, and [Figure 18](#) shows photomicrographs of these structures and a ‘dual’ structure.<sup>193</sup>

The test operates at a potential above  $2.00 \text{ V}$  (versus SHE), and the ‘ditch’ structure obtained with sensitized alloys must be due, therefore, to the high rate of dissolution of the sensitized areas as compared with the matrix. The ‘step’ structure is due to the different rates of dissolution of different crystal planes, and the ‘dual’ structure is obtained when chromium carbides are present at grain boundaries, but not as a continuous network.

#### 2.34.10.6 Electrochemical Tests

The difficulties associated with the ASTM ‘Standard Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels’ (A 262) are that the methods are destructive and qualitative in nature. Early attempts to develop quantitative, non-destructive electro-chemical techniques to detect

**Figure 17** ‘Ditch’ and ‘step’ structures. Reproduced from Streicher, M. A. J. *Electrochem. Soc.* **1959**, *106*, 161.

**Figure 18** Micrographs of (a) step, (b) ditch, and (c) dual structures. Reproduced from Streicher, M. A. *J. Electrochem. Soc.* **1959**, *106*, 161; Cowan, R. L.; Tedmon, C. S., Jr. In Fontana, M. G., Staehle, R. W., Eds.; *Advances in Corrosion Science and Technology*; Plenum Press: New York, 1973; Vol. 3.

sensitization by Clerbois *et al.*<sup>194</sup> employed potentiostatic techniques and it was observed that sensitized 18–8 stainless steel when anodically polarized potentiostatically in 1.0 mol dm<sup>-3</sup> H<sub>2</sub>SO<sub>4</sub> gave rise to a secondary active peak in the range 0.14–0.24 V (versus SHE) that was not present in the curve for the annealed alloys. This observation was criticized by France and Greene,<sup>195</sup> who consider that the active peak is due to the dissolution of Ni that had accumulated at the surface during active dissolution at lower potentials. Clerbois, *et al.*<sup>194</sup> also noted that if a sensitized sample is held at 0.14 V in 1.0 mol dm<sup>-3</sup> H<sub>2</sub>SO<sub>4</sub> for 24 h and then bent around a mandrel, it fissures and cracks, and it can be seen from Figure 15 that at this potential the chromium-depleted grain boundary will corrode actively, whereas the matrix will be passive. The potentiostatic test using cracking to detect susceptibility is thus analogous to the acid-copper sulfate test.

France and Greene<sup>195</sup> proposed that it should be possible to predict service performance by potentiostatic studies of steels in the environments encountered in practice coupled with metallographic examination of the surfaces. They argued that many environments do not selectively attack the grain boundaries of sensitized stainless steels so that the use of costly preventative measures is unnecessary. Since the intergranular attack of austenitic stainless

**Figure 19** Intergranular corrosion plot for a sensitized cast CF-8 stainless steel (0.08% max C 8–11% Ni 18–21% Cr) in H<sub>2</sub>SO<sub>4</sub> at 40°C as a function of potential and acid concentration. Reproduced from France, W. D.; Greene, N. D. *Corros. Sci.* **1968**, *8*, 9.

steels occurs only in limited potential regions it should be possible to predict service performance provided these regions are precisely characterized.

In their studies, specimens of different sensitized steels were held at various constant potentials in different concentrations of the acid under study at various temperatures and the surfaces were then examined metallographically for intergranular attack. Data obtained in this way enabled E-concentration of acid diagrams to be produced showing the zones of general corrosion, fine intergranular corrosion and coarse intergranular corrosion for a given sensitized stainless steel in a given acid at various constant temperatures (Figure 19).

Streicher,<sup>196</sup> however, considered this approach to be unsound and pointed out that the short duration of the potentiostatic studies carried out by France and Greene cannot be used to predict long-term behavior in service. The prolonged dialogue between these workers<sup>197,198</sup> was well summarized in the review article by Cowan and Tedmon<sup>184</sup> who concluded that these particular potentiostatic tests cannot be

regarded as accelerated tests for service environments and that predicting future industrial service for periods longer than the test is not advisable.

### 2.34.10.7 EPR Test

The electrochemical potentiokinetic reactivation (EPR) test was proposed by Cihal *et al.*<sup>199</sup> and developed by Novak and others<sup>200–202</sup> as a fast, quantitative and nondestructive technique for establishing the degree of sensitization of austenitic stainless steels.

The test is accomplished by a potentiodynamic sweep from the passive to the active regions of electrochemical potential (a process referred to as reactivation) for a given alloy in a specific electrolyte, during which the amount of current resulting from the corrosion of the chromium-depleted regions surrounding the precipitated chromium carbide particles is measured. In a sensitized microstructure, the bulk of these particles are located at the grain boundaries and are particularly susceptible to corrosion in oxidizing acids. Proposed national and international standards on EPR testing specify 0.5 M H<sub>2</sub>SO<sub>4</sub> + 0.01 M KSCN at 30°C as the EPR test environment for sensitized austenitic stainless steels.

Three different forms of EPR test can be employed, designated as the single loop, double loop and reactivation ratio methods in Figure 20.

#### 2.34.10.7.1 Single loop EPR test

The single loop method requires the sample to be polished to a 1 μm finish and then passivated at +200 mV (SCE) for 2 min following which the potential is decreased at 1.67 mV s<sup>-1</sup> until the corrosion potential of approximately -400 mV (SCE) is reached. The reactivation process results in the preferential breakdown of the passive film in the chromium-depleted grain boundaries of sensitized material and an increase in the current through the cell. The area under the *E* versus log *I* curve (Figure 20a) is proportional to the electric charge, *Q*, measured during the reactivation process. On nonsensitized materials, the current density during the reactivation step is very low because the passive film remains essentially intact. A measure of the degree of sensitization is obtained by calculating the normalized charge, *P<sub>a</sub>*, where:

$$P_a(C\ m^{-2}) = Q/A$$

where *Q* = integrated charge during the reactivation scan, and *A* = grain boundary area ( $5.1 \times 10^{-3}$  exp

0.35 *G*, where *G* is the ASTM grain size at 100 × magnification).

Pitting caused by the dissolution of nonmetallic inclusions can increase the *P<sub>a</sub>* value. Consequently, the microstructures of specimens with a high *P<sub>a</sub>* value must be examined to identify the source of the elevated value. In general, *P<sub>a</sub>* values below 0.10 are characteristic of unsensitized microstructures, while sensitization is indicated if *P<sub>a</sub>* exceeds 0.4. Single loop tests are sensitive to mild degrees of sensitization but do not readily distinguish between medium and severely sensitized materials.

#### 2.34.10.7.2 Double loop EPR test

Details of this procedure are given in Japanese Industrial Standard JIS G 0580. The sample is ground to a 100 grit finish then placed in the test solution for about 2 min to establish the rest potential (about -400 mV (SCE) for AISI Types 304 and 304L stainless steel).

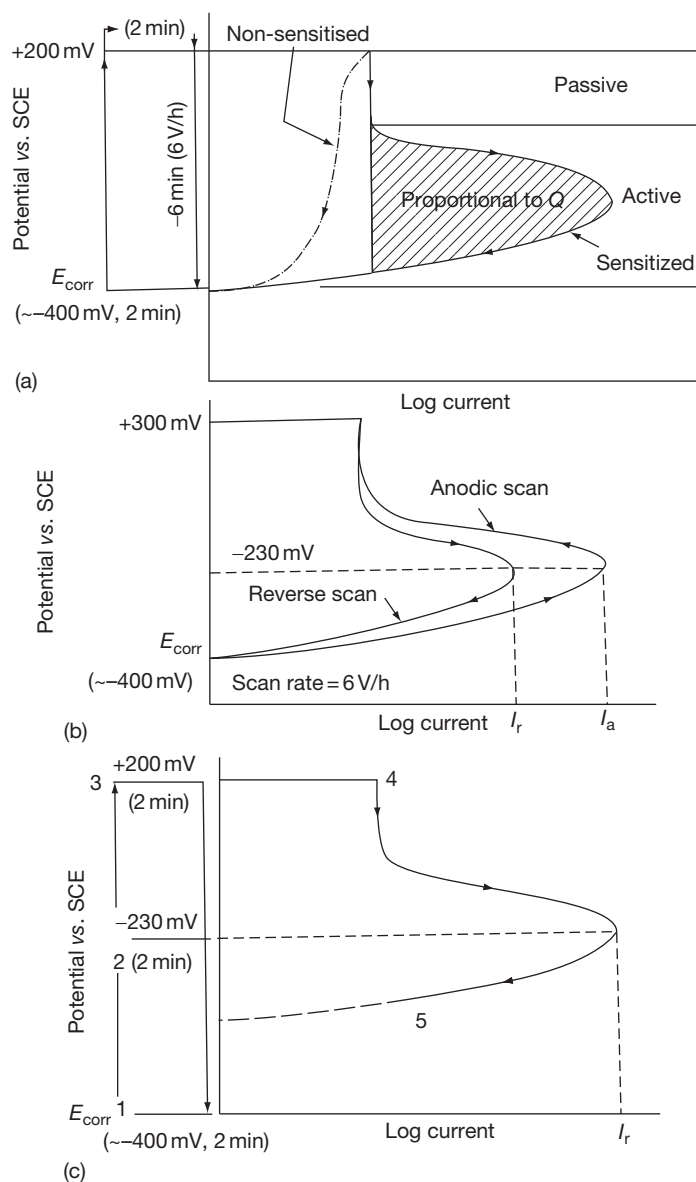

The sequence of polarization steps is shown in Figure 20b. The surface is first polarized anodically from the corrosion potential to +300 mV (SCE) at a rate of 1.67 mV s<sup>-1</sup>. As soon as this potential is reached, the scanning direction is reversed and the potential is decreased at the same rate to the corrosion potential. The ratio of the maximum current in the reactivation loop, *I<sub>r</sub>*, to that in the larger anodic loop, *I<sub>a</sub>*, is used as a measure of the degree of sensitization.

#### 2.34.10.7.3 Reactivation ratio EPR test

##### Figure 20c)

This is a simpler and more rapid method than the single or double loop tests, and depends on the fact that the value of *I<sub>a</sub>* determined during the anodic scan of a double loop test (which produces general dissolution without intergranular attack on sensitized material) is essentially the same for all AISI Type 304 and 304L steels.

The specimen is ground to a 100 grit finish then, after 2 min at the corrosion potential (about -400 mV (SCE)), it is conditioned by a 2-min treatment at -230 mV (SCE) in order to eliminate the need for polishing prior to the reactivation procedure. Passivation is then accomplished at +200 mV (SCE) for 2 min after which the specimen is reactivated by scanning back to the corrosion potential at 1.67 mV s<sup>-1</sup>. During this reactivation scan, the maximum current, *I<sub>r</sub>*, is measured and is divided by the surface area as an indication of the degree of sensitization.

**Figure 20** Schematics of reactivation polarisation curves. (a) Single loop EPR test method, and (b) double loop EPR test method, and (c) reactivation ratio EPR test method.

### 2.34.10.8 EPR Tests for Ferritic Stainless Steels

Lee<sup>203</sup> has demonstrated that in slightly modified forms the single loop EPR test can be used to quantify the degree of sensitization in ferritic stainless steels. For AISI Types 430, 430Ti, 430Nb, and 446 stainless steels, the test consists of passivating the specimen in deaerated 3 N  $\text{H}_2\text{SO}_4$  solution at 30 °C at +400 mV (SCE) for 10 min, followed by a reactivation at a scan rate of 250  $\text{mV min}^{-1}$ . The EPR test for AISI Type 434 stainless steel requires a

reactivating scan rate of 150  $\text{mV min}^{-1}$  (the other test conditions remaining unchanged). For AISI Type 444 stainless steel, the test is conducted in deaerated 5 N  $\text{H}_2\text{SO}_4$  solution at 30 °C and involves passivation at +400 mV (SCE) for 2 min followed by a reactivation at a scan rate of 100  $\text{mV min}^{-1}$ .

### 2.34.11 Crevice Corrosion and Pitting

Crevice corrosion and pitting are dealt with in some detail elsewhere, and it is not appropriate here to

discuss the nature of the phenomena nor the methods that have been used to determine the mechanisms of these forms of localized attack. However, it should be noted that many of the methods of testing follow directly from the concepts such as  $E_b$  (the critical pitting potential),  $E_p$  (the protection potential) have been investigated by a number of workers as possible criteria for the resistance of metals and alloys to pitting and crevice corrosion in service. It should also be noted that since crevice corrosion and pitting have similar mechanisms and since the presence of a crevice is conducive to pitting of alloys that have a propensity, to this form of attack, it is appropriate to consider them under the same heading. (Editor's note: A group of tests that have gained favor in recent years are based on the observation that, providing the solution is sufficiently oxidizing (or, equivalently, the potential is held at a suitably positive value), there is a critical temperature below which pitting will not occur, and a (more negative) critical temperature below which crevice corrosion will not occur. These are known as the critical pitting temperature (CPT) and critical crevice temperature (CCT), respectively, and the higher the temperature, the greater the resistance to pitting or crevice corrosion. There are various methods of measuring these temperatures (see ISO 17864, ASTM G 48, and G 150).)

In general, the tests may be classified as follows:

1. Laboratory tests, in which the specimen is immersed in a solution conducive to pitting, such as an acidified  $\text{FeCl}_3$  solution (redox potential above the critical pitting potential  $E_b$ ).
2. Laboratory tests, in which the specimen is anodically polarized in a chloride-containing solution to evaluate  $E_b$  and  $E_p$ .
3. Field tests, in which the specimen (with or without a crevice) is exposed to the environment that it will encounter in service.

As far as tests for crevice corrosion are concerned, all that is required is a geometrical configuration that simulates a crevice, which may be achieved in a variety of ways using either the metal itself or the metal and a nonmetallic material. Streicher<sup>204</sup> studied the crevice corrosion of Cr–Ni–Fe alloys, in which two plastic cylinders are held on the two opposite faces of a sheet metal specimen by two rubber bands, thus providing three different types of crevice in duplicate. A simple method of testing for crevice corrosion produced by contact with different materials is to use a horizontal strip of the metal under study and place on its upper surface at

intervals small piles of sand, small piles of sludge, pieces of gasket material, rubber, etc. More precise crevices can be produced by bolting together two discs of the metal, which are machined on the facing surfaces so that there is a flat central portion followed by a taper to the periphery of the disc, the flat central portion providing a very fine crevice and the tapered portion a coarser one.<sup>205</sup>

Figure 21 shows the types of crevices used by Wilde<sup>206</sup> for studying crevice corrosion and pitting of Cr–Ni–Fe alloys in the laboratory and in the field. Types 1 and 5 were used for anodic polarization studies in nitrogen-saturated  $1 \text{ mol dm}^{-3}$  NaCl and in aerated 3.5 wt% NaCl, respectively, and it can be seen that attachment to the conducting lead is by means of a Stern-Makrides pressure gasket; Types 3 and 4 were used for field tests in seawater for periods up to 4½ years; Type 2 was used for laboratory studies in which the specimens were immersed in acidified  $\text{FeCl}_3$  ( $108 \text{ g l}^{-1}$   $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  with the pH adjusted to 0.9 with HCl).

The value of electrochemical evaluation of the critical pitting potential as a rapid method of determining pitting propensity is controversial. France and Greene<sup>207</sup> studied the pitting of a ferritic steel (Type 430) using a controlled potential test in 1 M NaCl and a conventional immersion test in oxygen-saturated 1 M NaCl but found that at the same potential ( $-0.17$  to  $0.09 \text{ V}$  versus SCE) the corrosion rates were  $390$  and  $5.2 \text{ mm year}^{-1}$ , respectively. Similar studies were carried out on Zr using  $0.5 \text{ M H}_2\text{SO}_4 + 1 \text{ M NaCl}$  for the controlled potential test and  $0.5 \text{ M H}_2\text{SO}_4 + \text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  for the immersion test, and again the former gave a much higher corrosion rate than the latter. France and Greene conclude that these two types of test give rise to significantly different results under identical test conditions. To explain the results obtained with the ferritic stainless steel, they pointed out that, during the controlled potential test, the anodic reaction occurs at the metal's surface whereas the interdependent cathodic reaction takes place at the counter-electrode. Under these circumstances, the metal ions produced anodically result in increased migration of  $\text{Cl}^-$  to maintain electro-neutrality, and this in turn results in a higher concentration of  $\text{Cl}^-$  at the metal–solution interface with consequent increase in the rate of pitting. A similar situation does not arise during the immersion test where the anodic and cathodic sites are in close proximity, and charge balance is maintained without the migration of  $\text{Cl}^-$  from the bulk solution.

Potentiostatic tests<sup>208–210</sup> have been used, and Wilde and Williams<sup>208</sup> in potentiokinetic studies of

**Figure 21** Various types of crevices used for investigating crevice corrosion of stainless steels. Reproduced from Wilde, B. E. *Corrosion* **1972**, 28, 283.

the critical breakdown potential of stainless steels (Types 430 and 304) in 1.0 M NaCl showed that the nature of the gas used to purge the solution has a pronounced effect on the value of  $E_b$  (Table 5). In particular, they have established that the presence of dissolved  $O_2$  enhances passivity thus causing  $E_b$  to become more positive, and consider that this explains the failure of France and Greene to obtain accord between controlled potential tests in hydrogen-saturated chloride solutions and immersion tests in oxygenated chloride solutions at the same potentials.

Wilde and Williams<sup>208</sup> have used the redox system  $0.1 \text{ M } \text{Fe}(\text{CN})_3^{6-}/\text{Fe}(\text{CN})_4^{6-}$  for their immersion tests, which for Type 403 stainless steel gives a corrosion potential of  $-0.100 \text{ V}$  (versus SCE); selection of this system was based on the premise that being large anions they would be less likely than dissolved  $O_2$  to be involved in the adsorption processes that stabilize the passive state. Pitting occurred within 60 s, and equivalent tests on the same alloy conducted potentiostatically at  $-0.1 \text{ V}$  (versus SCE) in hydrogen-saturated 1.0 M NaCl gave similar results. They conclude that these two tests give comparable results, but that extreme caution must be used in utilizing  $E_b$  as an index of pitting, since its value is dependent upon environmental variables and in particular the nature of the dissolved gas in the corrodent. Wilde and Williams<sup>211</sup> have also shown that the critical pitting potential can be used to predict the behavior of alloys

**Table 5** Variation in  $E_b$  (V) for stainless steels in 1.0 mol  $\text{dm}^{-3}$  NaCl at 25 °C with nature of dissolved gas ( $E_b$  vs. SCE)

Gas	Type 430 stainless steel	Type 304 stainless steel
Hydrogen	-0.185	-0.050
Nitrogen	-0.130	-0.020
Argon	-0.100	+0.050
Oxygen	-0.035	+0.065

Data after Wilde and Williams<sup>208</sup>

exposed for long periods to seawater or to industrial chemical environments.

In a subsequent paper, Wilde<sup>206</sup> pointed out that although  $E_b$  is qualitatively related to resistance of a material to breakdown of passivity and pit initiation, it is of questionable value in predicting performance when crevices are present. Wilde found that although the Fe-30Cr-3Mo alloy appeared to indicate total immunity to breakdown when tested anodically in 1 M NaCl and in the freely corroding condition in 10%  $\text{FeCl}_3$ , it pitted within the crevice when an artificial crevice was present. Exposure in seawater for a 16-month period showed that AISI Types 304 and 316 stainless steels and the Fe-30Cr-3Mo alloy all pitted to the same extent when a crevice was present, although the former two alloys are considered to be less resistant to pitting than the Fe-30Cr-3Mo alloy. Pourbaix *et al.* have defined the protection

potential  $E_p$  as the potential below which no pits can initiate and preexisting pits cannot propagate, since they are passive at that potential. However, Wilde, using cyclic potentiodynamic sweeps at varying sweep rates, has established that  $E_p$  is not a unique parameter and that it varies in a semilogarithmic manner with the extent of localized attack produced during the anodic polarization, that is,  $E_p$ -log(extent of pit propagation) is linear. Thus, at a sweep rate of  $10 \text{ V h}^{-1}$ ,  $E_p$  was found to be  $-0.290 \text{ V}$  (versus SCE) while it fell to a more negative value of  $-0.410 \text{ V}$  at the slower sweep rate of  $1 \text{ V h}^{-1}$ . This was explained by Wilde as being due to the chemical changes that occur in the growing pit by hydrolysis of corrosion products and by the increased migration of  $\text{Cl}^-$  ions. Since  $E_p$  is a variable that depends upon experimental procedures, it cannot be used on its own as a criterion for protection against the propagation of preexisting pits or crevices in an engineering structure. Wilde considers that a more useful parameter appears to be the 'difference potential' ( $E_b - E_p$ ), which is used as a rough measure of the hysteresis loop area produced during the cyclic determination of  $E_b$  and  $E_p$ . (Editor's note: The parameter  $E_b - E_p$  has recently formed the basis of a predictive model of localized corrosion of Alloy 22 for the storage of nuclear waste over periods of up to a million years.) The area of the hysteresis loop obtained in a potentiodynamic sweep using a specimen with an artificial crevice provides a measure of the resistance to crevice corrosion in service, that is, the greater the area the lower the resistance. **Figure 22** shows the linear relationship between the 'difference potential' and the mass losses of various stainless alloys containing an artificial crevice that have been exposed to seawater for  $4\frac{1}{2}$  years.

**Figure 22** Linear correlation between difference potential and mass loss of various stainless steels containing crevices exposed to seawater for 4.25 years. Reproduced from Wilde, B. E. *Corrosion* **1972**, 28, 283.

These considerations show that although considerable advances have been made in developing laboratory controlled potential tests for evaluating crevice corrosion and pitting, the results must be interpreted with caution.

Guidance on crevice corrosion testing of iron-base and nickel-base stainless alloys in seawater and other chloride-containing aqueous environments is given in ASTM G 78, while ASTM G 61 provides a standard test method for conducting cyclic potentiodynamic polarization measurements for localized corrosion susceptibility (i.e., pitting and crevice corrosion) of iron-, nickel-, and cobalt-based alloys. Guidance on the selection of procedures for the identification and examination of pitting corrosion to determine the extent of its effect is available in ASTM G 46.

### 2.34.12 Impingement Tests/Erosion Corrosion

The method most commonly used for testing condenser materials is the BNFMR May jet impingement test<sup>212</sup> in which small sections of tube, abraded to a standard finish, are immersed in seawater and subjected to an underwater jet of seawater containing air bubbles. However, at high velocities, cavitation can occur in the water box in this test. An alternative design has been described to overcome this.<sup>213</sup> Resistance to impingement attack is also assessed by the Brownsdon and Bannister test<sup>214</sup> in which a stream of air bubbles is directed onto the surface of the test specimens immersed in seawater or sodium chloride solution. Special tests for resistance to corrosion under localized heat transfer conditions (hot-spot corrosion) have been described by Breckon and Gilbert<sup>215</sup> and by Bem and Campbell,<sup>216</sup> but temperature effects are usually ignored when comparing condenser tube materials.

Campbell<sup>217</sup> points out that in evaluating condenser tube materials a test apparatus is required that will include all the principal hazards likely to be encountered in service and should thus cater for the following conditions: impingement, slow moving water, heat transfer, and shielded areas. Furthermore, the internal surfaces should not be abraded, as in the jet impingement test, but should be tested in the 'as-manufactured' condition, particularly in view of the deleterious effect of carbon films produced during manufacture. LaQue has pointed out the importance of specimen area in impingement tests.<sup>218</sup>

The general arrangement of the apparatus is shown in **Figure 23**. It accommodates 10 vertical

**Figure 23** Campbell test apparatus for determining the various forms of attack suffered by condenser tubes in service. Reproduced from Campbell, H. S. MP577, BNFMR, 1973.

200 mm lengths of condenser tube spaced equally around a 125-mm diameter circle. Water enters the bottom of each tube through an inlet nozzle (Part No. 6 in Figure 23) which fits inside the tube and also locates it. The nozzle has a 5-mm diameter blind hole up the center connecting with a 2.4-mm diameter hole, set at 45° to the vertical, through which the water emerges at a velocity of  $10 \text{ m s}^{-1}$  to impinge on the wall of the tube. The water then rises up through the tube at a mean velocity of  $0.1 \text{ m s}^{-1}$  (in a 22–24-mm diameter condenser tube) and leaves

through an outlet nozzle (Part No. 1) fitted into the top end of the tube. Half the length of each outlet nozzle has a 2° taper on the outside to provide a reproducible annular crevice between it and the inside of the condenser tube. Neoprene 'O'-rings (Part No. 3) provide seals between the tube and the top and bottom nozzles, and the tubes are held in place by a common clamping plate (Part No. 2) at the top. The 10 inlet nozzles are fed with water through a distributor (Part Nos. 7, 8, and 15) of the design used in the May jet impingement apparatus, which ensures equal

distribution of water between them. The distributor and nozzles are all of nonmetallic materials. The part of each test piece between 40 and 65 mm from the top is fine-machined externally to fit a semicircular notch in a 15-mm thick brass heater block (Part No. 4), the tubes being held in contact with the block by a circumferential clip to ensure efficient and equal heat transfer between the block and each tube. The diameter of the inlet and outlet nozzles and that of the semicircular notches in the heater block are made to suit the size of condenser tube to be tested.

The common heater block shown in [Figure 23](#) can itself be subject to corrosion leading to different heat transfer conditions for different tubes, and in some later versions of the apparatus, individual short heating jackets are used for each tube, which are heated with oil from either a steam-heated or electrically heated heat exchanger. This modification not only avoids corrosion problems but also obviates the necessity to machine a length of the outside of each tube to fit the semicircular notches in the single heater block. The oil flow is adjusted to give an oil temperature of 95 °C at each outlet.

The test usually lasts 8 weeks, after which the tubes are sectioned longitudinally and their interiors inspected for accumulated deposits. Loose deposits are then removed by washing in water and the internal surfaces are examined for impingement attack, pitting and blistering or flaking of the corrosion-product film, using a low-power binocular microscope. After cleaning the section in 10% H<sub>2</sub>SO<sub>4</sub>, the depth of impingement attack, pitting, or other localized corrosion, is determined. Observations and measurements are recorded for each of the following five areas of the section: (a) impingement area opposite the inlet nozzle where water velocity and turbulence are greatest, (b) the slow-moving cold water area from the impingement area upward to the heated area, (c) the heated area including the heat-transfer area itself and the warm-water area above, and (d) the two annular crevices formed between the tapered portions of the cold-water inlet and warm-water outlet nozzles and the tube wall.

The Campbell apparatus is cheap to construct and easy to use and can be installed on site to assist the selection of condenser or heat-exchanger tube materials, or to monitor changes in the corrosivity of the cooling water. The information that it provides on the various forms of attack is more comprehensive than that of any other existing apparatus for corrosion testing condenser tubes, and it is therefore particularly suitable also for assessing new materials or the effect of surface conditions arising from changes in manufacture.

Impingement and erosion–corrosion forms of attack will usually be intensified by the presence of solid particles in the fluid. Variations of the jet test have been proposed to take this effect into account.<sup>219</sup>

Test equipment for the study of erosion–corrosion by liquids with sand content, as met in formation waters in oil and gas production, has been described by Kohley and Heitz.<sup>220</sup>

### 2.34.13 Corrosion Fatigue

The simultaneous action of alternating stresses and corrosion usually has a greater effect than when either is operating separately, and in this respect corrosion fatigue is analogous to stress–corrosion cracking. The important factors in corrosion fatigue include the following:

1. environmental conditions;
2. magnitude of the alternating stress;
3. magnitude of mean stress;
4. frequency of reversal of the stress;
5. load-versus-time waveform;
6. characteristics of the metal.

Depending on the intended purpose, corrosion fatigue tests can be conducted on smooth, notched or precracked specimens as well as on components and parts joined by welding. Because of the time-dependent nature of corrosion processes, it is essential that the mechanical variables employed during corrosion fatigue testing, including cyclic frequency and load-versus-time waveform, as well as the chemical and electrochemical conditions, are relevant to the intended application. For example, it is unlikely that data generated in a laboratory test at a frequency of 10 Hz would be applicable for predicting corrosion fatigue behavior in a structure that is cycled at 0.1 Hz.

Laboratory corrosion fatigue tests can be classified as either cycles to failure (crack initiation) or crack propagation tests.<sup>221</sup> Cycles to failure tests employ plain or notched specimens to provide data on the intrinsic corrosion fatigue crack initiation behavior of a metal or alloy. Crack propagation tests use precracked specimens to provide information on the threshold conditions for the propagation of preexisting defects by corrosion fatigue and on the rates of corrosion fatigue crack growth.

It is often difficult to conduct laboratory tests in which both the environmental and stressing conditions approximate to those encountered in service.

This applies particularly to the corrosive conditions, since it is necessary to find a means of applying cyclic stresses that will also permit maintenance around the stressed areas of a corrosive environment in which the factors that influence the initiation and growth of corrosion fatigue cracks may be controlled. Among these factors are electrolyte species and concentration, temperature, pressure, pH, flow rate, dissolved oxygen content, and potential (free corrosion potential or applied).

For tests on plain or notched specimens, a simple approach can be to use a conventional Wöhler rotating cantilever beam modified so as to permit the specimen to be brought into contact with the corrodent. This may be achieved by surrounding the specimen with a cell through which the corrosive solution is circulated or by applying it by a pad,<sup>222</sup> wick,<sup>223</sup> or drip feed.<sup>224</sup> Four-point loading or push-pull machines can be used in a similar way and have the advantage over the Wöhler machine when testing plain specimens that the length of the test-piece between the two points of loading is subjected to an approximately uniform stress.

Rawdon<sup>225</sup> used flat specimens that were subjected to repeated flexure while they were being immersed periodically in the corrosive solution. Kenyon<sup>226</sup> used a rotating wire specimen in the form of a loop, the upper part of which was attached to the motor while the lower part of the loop passed through the corrodent, and a somewhat similar device was developed by Haigh-Robertson and used in several studies.<sup>227,228</sup> Gough and Sopwith<sup>229,230</sup> used this machine in their studies, the corrodent being applied as a spray.

Figure 24 shows a slow fatigue machine<sup>231</sup> that has been developed to study the performance of welded butt and fillet joints for steels used in the construction of North Sea oil drilling rigs; the bending stress and frequency have been selected to simulate the forces produced by the wave motion. The specimens,  $1500 \times 100 \times 12.5$  mm with the weld 25 cm from the base, are clamped at the lower end, and the stress is applied as a variable bending moment at the upper end by rams. The rams, which are attached to a sliding frame, are activated by a pneumatic cylinder that can be automatically programmed for stroke and frequency and the stress level is monitored by strain gauges. The stress range is up to 300 MPa, and the frequency can be varied from 0.5 to 0.05 Hz. The corrodent is artificial seawater, and provision is made for studying the effect of cathodic protection by means of Zn anodes.

**Figure 24** (a) Rig for the laboratory study of corrosion fatigue of welded joints in seawater and (b) view of the test pieces showing welded joint. Reproduced from Jarman, R. A.; Smith, S.; Williams, R. A. *Br. Corros. J.* **1978**, *13*, 195.

Hoeppner<sup>232</sup> pointed out that until the early 1970s, most investigators conducted fatigue tests utilizing rotating bending, flat-plate bending or torsion-type loading configurations, which have the disadvantage that tests at positive or negative mean-stress values are difficult to achieve. In addition, the rotating bending and flat-plate bending tests create complex stress states upon crack initiation, for example, a shifting neutral axis. For these reasons, axial load fatigue machines, as recommended by the ASTM Committee E9, are preferred.

The results obtained from the tests described earlier are presented in the form of the conventional S-N curve, where S is the stress and N the number of cycles to cause fracture. Curves of this type are

obtained for the metal in air and for the metal in the corrodent, and comparison provides information on the effect of the corrosive environment on the fatigue life. Hoepfner points out that even though the S-N curve for either notched or unnotched specimens may be useful for certain applications it cannot always be employed to evaluate the effect of the environment on the fatigue life. This is because in some materials the inherent metallurgical and fabrication discontinuities, which may be undetectable by nondestructive testing will be so large that the only factor of engineering significance will be the rate of propagation of a crack from the initial defect, that is, the fatigue-crack propagation rate may play the dominant rôle in the useful life of the component. For this reason, it is important to conduct fatigue crack growth tests on precracked specimens, and the data are then presented in the form of curves showing crack growth rate,  $da/dN$ , versus stress intensity factor range,  $\Delta K$ .

The NACE publication *Corrosion Fatigue*<sup>232</sup> gives a comprehensive account of all aspects of the subject, and in this work, a review of the application of fracture mechanics for studying the phenomenon has been presented by McEvily and Wei,<sup>233</sup> while Kitagawa<sup>234</sup> has given a detailed account of crack propagation in unnotched steel specimens. This work should be consulted for details of testing and interpretation of results.

Special requirements for fatigue testing in aqueous environments are addressed in the Annexe to ASTM E 647 'Standard Test Method for Measurement of Fatigue Crack Growth Rates.'

### 2.34.14 Cavitation-Erosion

In considering these tests, it should be remembered that the phenomenon of cavitation-erosion is often accompanied by corrosion effects and that a synergistic effect may operate between the mechanically and chemically induced forms of attack. In fact the term cavitation-erosion-corrosion may often be more applicable in describing the requirements of a test procedure. The subject has been discussed by Wood and Fry.<sup>235</sup>

The methods used have been classified by Lichtman, *et al.*<sup>236</sup> as follows:

1. High-velocity flow.
  - a. Venturi tubes.
  - b. Rotating discs.
  - c. Ducts containing specimens in throat sections.

2. High-frequency vibratory devices.
  - a. Magnetostriction devices.
  - b. Piezoelectric devices.
3. Impinging jet.
  - a. Rotating specimens pass through continuous, stationary jets or droplets.
  - b. Stationary specimens exposed to high-speed jet or droplet impact.

All tests are designed to provide high erosion rates on small specimens so that the test can be conducted in a reasonable time, and although vibratory and high-velocity jet methods may not simulate flow conditions, they give rise to high-intensity erosion and can be used, therefore, for screening materials.

The essential component of many high-velocity flow rigs is a venturi-type section in which cavitation occurs in the low-pressure high-velocity region created by the venturi throat. Typical of this type is the double-weir arrangement used by Schroter,<sup>237</sup> but since this technique requires very large volumes of water, it is not readily adaptable to laboratory use. Hobbs<sup>238</sup> and others have used a uniform-area, rectangular-cross-section duct in which a cylinder of small diameter is inserted; cavitation occurs in the wake of the cylinder, which may be used as the test specimen or the specimen may be set in the side wall of the duct near the cylinder. The cavitation intensity will be dependent on the configuration of the test section and the velocity, pressure, temperature, viscosity, surface tension, corrosivity, gas content, and density of the liquid.

Devices in which cavitation is achieved by vibrating a test specimen at high frequencies are often used. The original apparatus was developed by Gaines<sup>239</sup> and was adapted for cavitation-erosion studies by Hunsaker and Peters, as described in the paper by Kerr,<sup>240</sup> and it has been used also by Beeching,<sup>241</sup> Rheingans,<sup>242</sup> and Leith and Thompson.<sup>243</sup> In this method, cavitation is produced by attaching the specimen to the vibrating source or by means of a partially immersed probe vibrating axially at a high velocity and low amplitude and placed close to the test specimen. Although originally magnetostriction oscillators were used,<sup>239</sup> these have now been largely superseded by piezoelectric oscillators, which are more efficient. The apparatus consists basically of a conventional ultrasonic generator, a piezoelectric transducer and a resonating horn or probe, and tests are typically carried out at a frequency of 20 kHz.

Originally, the test specimen was fastened to the end of the ultrasonic probe, and this is still specified

in ASTM D 2809 which describes a method of testing aluminum in antifreeze solution. However, this arrangement also subjects the test-piece to high alternating stresses as a result of the high accelerations associated with vibration at ultrasonic frequencies, which may be overcome by using a stationary test-piece and locating it immediately below a dummy tip placed on the end of the ultrasonic probe.

Vibratory test apparatuses are relatively cheap to build and run and have low power consumption, while flow rigs are bulky, expensive to build and run, and have high power consumptions but have the advantage that they simulate more closely practical conditions of hydrodynamic cavitation. On the other hand, the damage rate is higher in the vibratory tests than in the flow test, although whether this is advantageous depends on the objectives of the test. A further criticism of the vibratory test is that the mechanical component is overemphasized in relation to the effect produced by corrosion. For this reason Plesset<sup>244</sup> uses a technique in which cavitation is intermittent with short bursts of vibration followed by longer static periods, which significantly increases the erosion rate of materials with poor corrosion resistance but has little effect on materials with good corrosion resistance. Tests of this type have distinguished readily between materials having the same hardness but different resistances to corrosion, and between corrosive and noncorrosive solutions.

Figure 25 shows an apparatus for studying cavitation-corrosion using the magnetostriction

principle for vibration. A nickel tube is made the core of a magnetic field tuned to the natural frequency of the tube assembly, and since nickel changes its length as it is magnetized and demagnetized, it will vibrate with the frequency of the magnetizing current. The specimen under test vibrates with the nickel tube, and a commonly used frequency is 6500 Hz with an amplitude of 0.008–0.009 cm. Damage is increased by the amplitude of vibration, and the more resistant the material the greater the amplitude to achieve substantial attack. Increase in temperature decreases damage by increasing the vapor pressure within the cavitation bubbles, thus reducing the force of their collapse, but in opposition to this effect is the increased damage resulting from the lower solubility of gases which cushion the collapse of the cavitation bubbles. Consequently, under many circumstances damage reaches a maximum at a test temperature of about 46–52 °C.

Assessment of cavitation-erosion is based on mass loss, and the results are expressed as curves showing cumulative mass (or volume) loss versus the time of the test. Eisenberg and Preiser<sup>245</sup> have expressed the cumulative mass-loss plot on the basis of the rate versus time curve as follows:

1. Incubation zone (little or no mass loss).
2. Accumulation zone (increasing rate to a maximum).
3. Attenuation zone (decreasing loss rate to a steady-state value).
4. Steady-state zone (loss rate at a constant value).

Figure 25 Vibratory cavitation-erosion test using magnetostriction.

It has been proposed that evaluation of the resistance of materials, or the study of experimental variables, should be based on the results obtained for the attenuation zone. Other methods of assessment have been proposed by Hobbs,<sup>246</sup> and by Plesset and Devine.<sup>247</sup>

Examples of various vibratory test procedures for studying cavitation-erosion of metals in inhibited engine coolants have been given in an ASTM Special Technical Publication.<sup>248–250</sup>

### 2.34.15 Fretting Corrosion

The deterioration of surfaces that occurs when parts supposedly tightly fitted together nevertheless move slightly relative to each other in some sort of cycle under load is called fretting corrosion. With ferrous materials, the characteristic corrosion product is a finely divided cocoa-colored oxide. The general state of knowledge of the subject was reviewed in a symposium on fretting corrosion held by the ASTM in 1952<sup>251</sup> and more recently by Waterhouse.<sup>252,253</sup>

Several techniques for reproducing fretting corrosion have been used. All involve some means for controlling contact pressure, and for achieving and measuring small-amplitude cyclic motion or slip between the contacting surfaces; some control of the environment, particularly moisture, which has a considerable effect on the extent of damage, is also desirable. Fink<sup>254</sup> used an Amsler wear machine. Another early series of tests on fretting corrosion arose from a study of the bottom bearings of electricity meters by Shotter.<sup>255</sup> Tomlinson *et al.*<sup>256</sup> adapted a Haigh alternating-stress machine by which annular specimens were pressed together under load while being subjected to vibration to achieve the required slip. These investigators also used apparatus in which a specimen having a spherical surface was moved cyclically through a small amplitude while in contact under load with a plane surface. A further modification involved an upper specimen machined to provide an annulus which was oscillated under load in contact with a lower plane specimen. A similar technique was used by Wright.<sup>257</sup> The area of damage was measured optically, and the maximum depth of damage was calculated by carefully lapping the lower surface and determining the change in mass. In addition, the amount of oxidized debris was determined chemically.

Uhlig *et al.*<sup>258</sup> measured fretting damage by mass loss of recessed 25.4-mm diameter steel cylinders subjected to radial oscillating motion. The specimens were loaded pneumatically, frequency was varied,

and slip was adjusted up to 0.020 mm. Mass loss was determined after debris had been removed by pickling the specimens in inhibited acid.

McDowell<sup>259</sup> used a setup that took advantage of the elastic modulus of one of the test materials to provide a definite deflection subject to control. A rotating-beam fatigue-testing machine was used to produce an alternating compressive and tensile deflection on the surface of the rotating specimen. A sliding specimen slipped back and forth on the rotating specimen as the outer fibers were strained alternately in tension and compression in proportion to the extent of deflection of the rotating specimen.

Horger<sup>251</sup> undertook rotating-beam fatigue tests of press-fitted assemblies using specimens as large as 305-mm diameter shafts.

Warlow-Davies<sup>260</sup> used a technique in which specimens were subjected to fretting corrosion and then tested in fatigue to show the effect of fretting damage in lowering resistance to fatigue.

Herbeck and Strohecker<sup>251</sup> used machines designed particularly for comparing the merits of lubricants in preventing fretting corrosion of anti-friction bearings. One provided for both oscillating conditions and combination radial and thrust loads to simulate service. Another was concerned primarily with thrust bearings and correlated satisfactorily with the radial load tester.

An interesting approach involved microscopic observation of fretting corrosion; a glass slide mounted on the stage of a microscope was used for the bearing surface which pressed against a spherical specimen being vibrated by a solenoid.<sup>261</sup>

Other testing machines and techniques have been described by Gray and Jenny,<sup>262</sup> de Villemeur,<sup>263</sup> Wright,<sup>264,265</sup> Barwell and Wright,<sup>266</sup> Field and Waters,<sup>267</sup> and Waterhouse.<sup>268</sup>

### 2.34.16 Corrosion Testing in Liquid Metals and Fused Salts

Liquid metals have high heat capacities and heat transfer coefficients, and these and other properties make them attractive as coolants for high temperature nuclear reactors and as heat-transfer and working fluids in power-generation systems that operate in conjunction with nuclear reactors. However, austenitic cladding and ferritic structural steels can suffer rapid corrosion when exposed to liquid metals at high temperatures (e.g., in liquid sodium at temperatures above 600 °C or in liquid Pb-17 at %-Li eutectic alloy at

temperatures above 500°C). Similar corrosion processes affect numerous solid–liquid metal systems, including molybdenum in liquid sodium or lithium, stainless steel in liquid aluminum, platinum in liquid sodium, and carbon steel in liquid zinc.

Corrosion by liquid metals is usually controlled by diffusion processes in the solid and liquid phases and, unlike aqueous corrosion, does not generally involve galvanic effects, and, even where electrochemical phenomena are known to occur, it has not, in general, been demonstrated that they have been responsible for a significant portion of the corrosion observed.<sup>269</sup> In fused salts, there is evidence that electrochemical factors are involved.<sup>270,271</sup> Nevertheless, the corrosion process in relation to liquid metals and fused salts may conveniently be considered under one of the following processes, which do not directly include electrochemical factors: (1) chemical reaction, (2) simple solution, (3) mass transfer, and (4) impurity reactions. Several of these processes may be involved in a single corrosion reaction, but for simplicity, they will be treated separately.

#### 2.34.16.1 Chemical Reaction

This involves the formation of distinct compounds by reaction between the solid metal and the fused metal or salt. If such compounds form an adherent, continuous layer at the interface, they tend to inhibit continuation of the reaction. If, however, they are nonadherent or soluble in the molten phase, no protection will be offered. In some instances, the compounds form in the matrix of the alloy, for example, as grain-boundary intermetallic compound, and result in harmful liquid metal embrittlement (LME), although no corrosion loss can be observed.

#### 2.34.16.2 Simple Solution

The liquid phase may simply dissolve the solid metal, or the liquid may go into solid solution with the metal to form a new phase. In some instances, only a single constituent of an alloy will dissolve in the liquid phase; in this case, a network of voids extending into the metal will result, with obvious deleterious effects.

#### 2.34.16.3 Mass Transfer

This phenomenon manifests itself as the physical transport of a metal from one portion of the system to another, and may occur when there is an alloy compositional difference or a temperature gradient

between parts of the unit joined by the flowing liquid phase. An exceedingly small solubility of the metal component or corrosion product in the molten metal or salt appears sufficient to permit mass transfer to proceed at a fairly rapid pace.

#### 2.34.16.4 Impurity Reactions

Small amounts of impurities in the liquid phase or on the surface of the solid metal may result in the initiation of attack or in increased severity of attack by one of the mechanisms just outlined.

In general, it is fair to state that one of the major difficulties in interpreting, and consequently in establishing definitive tests of, corrosion phenomena in fused metal or salt environments is the large influence of very small, and therefore not easily controlled, variations in solubility, impurity concentration, temperature gradient, etc.<sup>272</sup> For example, the solubility of iron in liquid mercury is of the order of  $5 \times 10^{-5}$  at 649°C, and static tests show iron and steel to be practically unaltered by exposure to mercury. Nevertheless, in mercury boiler service, severe operating difficulties were encountered, owing to the mass transfer of iron from the hot to the cold portions of the unit. Another minute variation was found substantially to alleviate the problem: the presence of 10 ppm of titanium in the mercury reduced the rate of attack to an inappreciable value at 650°C; as little as 1 ppm of titanium was similarly effective at 454°C.<sup>273</sup>

In the case of the alkali metals, impurities, such as oxygen and carbon, can have a significant effect on the corrosion of steel and refractory metals. Borgstedt and Frees<sup>274</sup> have shown that for the corrosion of both stabilized and unstabilized austenitic stainless steels in flowing liquid sodium at 700°C, there is an almost linear dependence of the corrosion constant,  $k$ , on the oxygen content of the sodium, as follows:

$$\log k = -5.6637 + 0.919 \log [\text{O}] \quad [17]$$

where,  $k$  is in  $\text{mg cm}^{-2} \text{h}^{-1}$  and  $[\text{O}]$  is in ppm. Barker *et al.*<sup>275</sup> have demonstrated that oxygen exerts a similarly deleterious effect on the corrosion of AISI Type 316 austenitic stainless steel in liquid Pb–17Li eutectic by increasing the depth of the ferritic corrosion layer and the extent of chromium depletion within the layer.

The effect of carbon on the corrosion of stainless steels in liquid sodium depends upon the test conditions and the composition of the steels.<sup>274</sup> Stabilized stainless steels tend to pick up carbon from sodium,

leading to a degree of carburization that corresponds to the carbon activity in the liquid metal. Conversely, unstabilized stainless steels suffer slight decarburization when exposed to very pure sodium. The decarburization may promote corrosion in the surface region of the material<sup>276</sup> and, under creep rupture conditions, can lead to cavity formation at the grain boundaries and decreased strength.

### 2.34.16.5 Testing

As in all corrosion testing, the procedure that most nearly duplicates the conditions anticipated in service will provide the most satisfactory and useful information for those aspects of corrosion under consideration here. In fact, in view of the extraordinary sensitivity of fused metal and salt corrosion phenomena to minute variations in operating conditions and purity of components, as already discussed, failure to reproduce these conditions with considerable accuracy may well make any test results completely unrealistic and worthless. In all of the following, then, it should be understood, if not explicitly stated, that all extraneous matter must be carefully excluded from the system and that only materials closely simulating those to be employed in service (including prior history and surface preparation of the metals) should be used. Other factors affecting the corrosion in liquid metals and fused salts include the heat flux of the corroding surface, the volume of liquid to the surface area of the solid, and the liquid flow rate. If, however, screening tests to establish the compatibility of a relatively large number of metals with a given molten metal or salt are to be run, it is often useful to commence with static tests even though the ultimate application involves a dynamic system. This is desirable because static tests are comparatively simple to conduct and interpret, and considerably more economical to operate, and because experience has shown that a metal that fails a static test is not likely to survive the more severe dynamic test.<sup>277</sup> Static tests have been used by Grabner *et al.*<sup>278</sup> to investigate the compatibility of metals and alloys in liquid Pb–Li eutectic at temperatures up to 650°C.

#### 2.34.16.5.1 Static tests

Ideally, a static test would consist of immersing a test sample in the liquid medium held in an inert container under isothermal conditions. Tests in mercury, for example, may be contained in glass at temperatures of several hundred degrees.<sup>279</sup> Unfortunately, at the higher temperatures and with the aggressive

metals and salts of interest, there are few readily available inert container materials, and results will often vary according to the nature of the container. The most satisfactory solution is to make the container of the same material as the test sample or, even in some cases, to let it be the sample. Klueh used small capsules for determining the effect of oxygen on the compatibility of Nb and Ta with sodium<sup>280</sup> and potassium.<sup>281</sup> For the Nb–K tests, the Nb specimen was approximately  $2.5 \times 1.4 \times 0.1$  cm and was contained in a Nb capsule surrounded by another capsule of welded Type 304 stainless steel. It was demonstrated that the oxygen concentration, added as K<sub>2</sub>O, markedly increased the solubility of the Nb in the molten K. DiStefano<sup>282</sup> studied the interaction of Type 316 stainless steel with Nb (or Nb–1Zr) in Na and Na–K by exposing tensile specimens of Nb (Nb–1Zr) to the liquid metal in a stainless steel container. Carbon and nitrogen from the stainless steel were transferred to the Nb, resulting in carbide-nitride at the surface and diffusion of nitrogen into the metal, thus producing an increase in tensile strength and a decrease in ductility. Close control of temperature is also essential if reproducible results are to be obtained, because of differential solubility as a function of temperature. For example, the corrosion rate for Cu–Bi at  $500 \pm 5.0^\circ\text{C}$  is several times its rate at  $500 \pm 0.5^\circ\text{C}$ .<sup>283</sup>

#### 2.34.16.5.2 Refluxing capsules

In systems in which a liquid metal is used as the working fluid, the liquid is converted to vapor in one part of the system, while the converse takes place in another, and the effect of a boiling-condensing metal on the container materials is most readily studied in a refluxing capsule. DiStefano and De Van<sup>284</sup> used a system in which the lower part of the capsule was surrounded by a heating coil, while the upper part was water cooled. Specimens were inserted in the upper part of the capsule and thus exposed to the condensing vapor, the rate of condensation being controlled by the water flow rate.

When close control of purity is essential, it may be necessary to assemble the test specimens in a dry box under an inert atmosphere and to weld the containers shut under inert gas or vacuum before placing on test. With some environments, even the small amount of oxygen and moisture adsorbed on the component surfaces will significantly affect the test results. In one laboratory, this problem was eliminated by maintaining within the dry box a container of molten sodium at  $250^\circ\text{C}$ <sup>277</sup>; it is a rather cumbersome procedure, but one that emphasises again the importance of purity.

Static test results may be evaluated by measurement of change of mass or section thickness, but metallographic and X-ray examinations to determine the nature and extent of attack are of greater value because difficulty can be encountered in removing adherent layers of solidified corrodent from the surface of the specimen on completion of the exposure, particularly where irregular attack has occurred. Changes in the corrodent, ascertained by chemical analysis, are often of considerable value also. In view of the low solubility of many construction materials in liquid metals and salts, changes in mass or section thickness should be evaluated cautiously. A limited volume of liquid metal could become saturated early in the test, and the reaction would thus be stifled when only a small corrosion loss has occurred, whereas with a larger volume, the reaction would continue to destruction.<sup>283,285</sup>

### 2.34.16.5.3 Dynamic tests

Various tests have been devised to study the effects of dynamic conditions, and one of the simplest tests is to use a closed capsule that contains a sample at each end and is partially filled with the liquid metal or salt.<sup>286</sup> A temperature gradient is maintained over the length of the tube, and the capsule is rocked slowly so that the liquid metal passes from one end to the other. After the test, the extent of mass transfer is determined from the two specimens placed at each end of the capsule. Tests of this type are useful to establish whether thermal-gradient mass transfer (or concentration-gradient mass transfer if dissimilar metals are incorporated in the system) will occur, but although the method is useful for screening purposes, the dynamic nature of the heating and cooling cycles prevents a rigorous analysis of mass transfer in terms of time and temperature.

High velocity effects can also be studied in spin tests using cylindrical specimens of the solid metal and rotating them at high velocities in an isothermal-metal bath. Although, strictly speaking, only a single alloy should be tested at a time, it is generally satisfactory to include a variety of alloys since the velocity effects become manifest at considerably shorter times than does mass transfer.

Kassner<sup>287</sup> used a rotating disc, for which the hydrodynamic conditions are well defined, to study the dissolution kinetics of Type 304 stainless steel in liquid Bi-Sn eutectic. He established a temperature and velocity dependence of the dissolution rate that was consistent with liquid diffusion control with a transition to reaction control at 860 °C when the speed of the

disc was increased. The rotating disc technique has also been used to investigate the corrosion stability of both alloy and stainless steels in molten iron sulfide and a copper/65% calcium melt at 1220 °C.<sup>288</sup> The dissolution rate of the steels tested was two orders of magnitude higher in the molten sulfide than in the metal melt.

### 2.34.16.5.4 Loop tests

Loop test installations vary widely in size and complexity, but they may be divided into two major categories: (1) thermal-convection loops and (2) forced-convection loops. In both types, the liquid medium flows through a continuous loop or harp mounted vertically, one leg being heated, while the other is cooled to maintain a constant temperature across the system. In the former type, flow is induced by thermal convection, and the flow rate is dependent on the relative heights of the heated and cooled sections, on the temperature gradient and on the physical properties of the liquid. The principle of the thermal convective loop is illustrated in **Figure 26**. This method was used by De Van and Sessions<sup>289</sup> to study mass transfer of niobium-based alloys in flowing lithium, and by De Van and Jansen<sup>290</sup> to determine the

**Figure 26** Loop test for studying corrosion in molten metals or salts.

transport rates of nitrogen and carbon between vanadium alloys and stainless steels in liquid sodium.

The thermal-convection loops are limited to flow velocities up to about  $6 \text{ cm s}^{-1}$ . Where higher velocities are required, the liquid must be pumped, either mechanically or electromagnetically; the latter is usually preferred as it avoids the problem of leakage at the pump seal. Basically, these forced-convection systems<sup>290–293</sup> consist of (1) a hot leg, where the liquid metal is heated to the maximum temperature, (2) an economiser or regenerative heat exchanger, and (3) a cold leg, where the liquid is cooled to its minimum temperature. The economiser consists of concentric tubes with the hotter liquid flowing through the inner tube, while the cooler liquid flows in the opposite direction through the annulus between the two tubes, thus minimizing power requirements. The material under test may be used for constructing all parts of the loop, and the loop is then destructively examined after a given period of test. However, this is costly, and it is now a usual practice to use the loop as a permanent testing facility and to test specimens that are generally placed in the hot leg. Assessment of corrosion is based on changes in weight, dimensions, composition, mechanical properties, and microstructure.

The final stage in a testing program is the design, construction, and testing of loops that simulate the type of system for which data are required.

Since sodium, which is liquid between about  $100^\circ\text{C}$  and  $881^\circ\text{C}$ , has excellent properties as a heat-transfer medium, with a viscosity comparable with that of water and superior heat conductivity,<sup>294</sup> much attention has been paid to liquid sodium corrosion testing of metal and alloys. Indeed, there was an ASTM Standard Practice, which was used for the determination of the corrosion of ferrous alloys, austenitic stainless steels, high nickel alloys, and refractory metals in pumped flowing sodium (ASTM G 68, now withdrawn). This included guidance on the monitoring and control of impurity levels in liquid sodium. The oxygen content of the liquid sodium can be measured continuously by an electrochemical oxygen meter.<sup>295</sup> Similar electrochemical sensors have been used to monitor the carbon content of liquid sodium<sup>296</sup> and the oxygen content of liquid Li–17Bi eutectic.<sup>297</sup> The purity of the liquid metal can be maintained by means of a cold trap through which a small part of the flow is continuously bypassed, the purity level being determined by the temperature of the trap. The ASTM Standard Practice gave the following relationship between the cold trap temperature and

oxygen content of the liquid sodium:

$$\log_{10} C(\text{ppm oxygen content}) = 7.0058 - 2820/T(^{\circ}\text{K}) \quad [18]$$

and recommended that the oxygen level of liquid sodium be lowered to 2.85 ppm or less, corresponding to a cold trap temperature of about  $150^\circ\text{C}$ . Borgstedt and Frees<sup>274</sup> found that a cold trap operating at  $125^\circ\text{C}$  further reduced the oxygen content of liquid sodium to 1–2 ppm and acted as a sink for carbon, reducing the level of this element to about 0.01 ppm. The maintenance of low impurity levels in the liquid metal is facilitated if the inert cover gas in the expansion chamber is of high purity (e.g.,  $\geq 99.996\%$  argon).

Although the thermal loop test approximates to the conditions that obtain in a dynamic heat-transfer system, in evaluating the results, it is necessary to be aware of those aspects in which the test differs from the full-scale unit, as otherwise unwarranted confidence may be placed in the data. Assuming that adequate attention has been paid to the purity and condition of components, etc., the following factors will, according to ASTM G 68, influence the observed corrosion behavior:

1. liquid metal temperature;
2. degree of nonisothermality of the liquid metal system;
3. liquid metal flow rate;
4. heat flux at the corroding surface;
5. surface-area/volume ratio of solid metal/liquid metal;
6. relative sizes of dissimilar metal surface areas exposed to the liquid metal at the various system temperatures.

The relation between corrosion, and maximum temperature and temperature gradient is obvious, since solubility varies as a function of temperature. If the results are to be useful, these factors should match those anticipated in service. Erratic temperature cycling should be avoided as this can also modify the corrosion behavior. The effect of surface-to-volume ratio will be more pronounced in thermal convection than in pump loops. It can readily be seen that if a relatively small volume of liquid passes through a given isothermal segment of loop per unit time, it will become saturated quickly, and the corrosion rate will appear lower than would be the case if a substantially larger volume of liquid were passing at the same velocity. In a pumped loop, the velocity can be maintained sufficiently high to prevent the attaining of equilibrium between the solid and liquid

phases, and the rate of dissolution of the solid will be the controlling step. The flow velocity, or Reynolds number, will affect this step too, in that increased velocity will decrease the stagnant or lamellar layer adjacent to the tube wall and decrease the diffusion path that particles must negotiate to enter the rapidly moving stream.<sup>283</sup> The turbulence of the flow may also be modified by the manner in which test specimens are inserted in the loop, and this should also be considered carefully in designing a test unit.

The corrosion rates of the materials of construction are always of importance, but it has been found that, the uniform removal of metal from the hot leg may not impair the load-carrying ability of the container, whereas the deposition of metal in the cold leg can cause the cessation of flow, and the measure of the suitability of an alloy is often the time, under given conditions, that it takes for plugging to occur. Again, the flow velocity and the cross-sectional area are of primary importance in relating test results to operating conditions.

The ultimate test, short of constructing a full-scale unit, is to build a small-scale system in which each item to be incorporated in the final device is represented. Such programs are too specialized to warrant discussion here, and are fully described in the literature.<sup>298–301</sup>

#### 2.34.16.6 Liquid–Metal Embrittlement

Metals have sometimes been observed to crack almost instantaneously when wetted by certain molten metals and subjected to plastic strain at temperatures far below those at which the diffusion-ruled processes involved in liquid–metal corrosion attain significance.<sup>302</sup> The fracture appears to be more brittle than in the absence of the liquid metal, leading to decreased elongation and reduction of area values and, in severe cases, brittle intergranular fracture. Like other forms of environmental cracking, liquid–metal embrittlement is highly specific according to alloy and environment. For example, molten zinc can cause liquid–metal embrittlement of stainless steel if the oxide film is damaged, and because of this molten zinc from associated galvanized parts poses the greatest hazard in welding stainless steel equipment.<sup>303</sup> Other well known examples of liquid–metal embrittlement include the effects of solder on copper alloys and carbon steels and those of mercury on aluminum and nickel alloys. It is generally accepted that most cases of liquid–metal embrittlement arise from the effects of chemisorption of liquid–metal atoms and

the consequent reduction of the tensile strength of interatomic bonds at the crack tip since rates of crack growth (up to  $10 \text{ cm s}^{-1}$ ) are usually rapid compared with rates of diffusion of embrittling atoms ahead of cracks or dissolution of the solid in the liquid metal.<sup>304</sup> However, there are a few cases in which diffusion of embrittling atoms ahead of cracks or selective dissolution of a particular phase of an alloy can produce degradation of materials in liquid–metal environments.<sup>305</sup>

Prerequisites for liquid–metal embrittlement are that a solid metal should be subjected to tensile plastic strain while wetted by a liquid metal in which it has low solubility. It has been suggested that such embrittlement may be a general phenomenon occurring under appropriate conditions and to varying degrees between all solid–metal/liquid–metal couples and that a single mechanism may be responsible for all liquid metal embrittlement failures.<sup>306</sup> The occurrence and severity of the embrittlement are governed by:

1. the particular solid–metal/liquid–metal combination;
2. the temperature;
3. the strain rate;
4. the initial mechanical and metallurgical state of the solid metal.

The most commonly used method for assessing liquid–metal embrittlement is by tensile deformation at a slow strain rate. During testing, the specimen should be immersed in the liquid metal in a sealed autoclave to avoid contamination by atmospheric gases.<sup>302</sup> Electrochemical probes similar to those employed in liquid metal corrosion testing can be used to monitor the purity of the liquid metal. Susceptibility to liquid–metal embrittlement can be assessed in terms of the uniform elongation, reduction in area, and fracture appearance of the specimen relative to that determined under similar testing conditions in an inert environment at the same temperature. Where information on crack-propagation behavior is required, use can be made of precracked specimens. These can be tested under static or cyclic loading conditions to determine threshold stress intensity factors and crack growth rates.<sup>307</sup>

#### 2.34.17 Tests in Plant

Although laboratory tests (NACE TMO 169, and Thompson)<sup>308</sup> are obviously of value in selecting materials, they cannot simulate conditions that

occur in practice, and although an initial sorting may be made on the basis of these tests, ultimate selection must be based on tests in the plant. This is particularly important where the process streams may contain small concentrations of unknown corrosive species whose influence cannot be assessed by laboratory trials. Testing is also important for monitoring various phenomena such as embrittlement, hydrogen uptake, corrosion rates, etc.

### 2.34.17.1 Corrosion Racks

Exposure of coupons or specimens to the process stream cannot be achieved satisfactorily unless they are rigidly supported in a rack, although in some cases, it may be possible to simply hang them in by means of a wire. Methods of exposure of coupons are described in ASTM Method G4.

In the birdcage rack, disc specimens are mounted on a central rod and are insulated from each other and from the rod by insulating spacers and an insulating tube, respectively. PTFE has been found to be suitable for this purpose in aggressive media, particularly at high temperatures. Plates at the end of the rack act as bumpers to prevent the specimens touching the side walls, and the assembly is constructed from a corrosion resistant material such as Monel. Advantages of this method are the following: (1) electrical insulation avoids galvanic effects, and (2) the method of holding the specimen at the centre avoids losses because of corrosion around the point of support. The disadvantages are as follows: (1) specimens are not subjected to either heating or cooling effects and thus will not disclose 'hot-wall' effects and may also escape corrosive condensates when the

specimens are in a vapor stream above the dew point, and (2) the corrosivity of the environment may be affected by the presence of corrosion products of the construction material of the racks or by corrosion products of adjacent specimens. A further disadvantage is that because of its size and shape, it must be inserted into the process stream when the plant is out of service. Special devices are required for mounting specimens within pipelines so that they will be subjected to velocity effects.

The insert rack is designed for easy installation and removal through an unused nozzle. The supporting rods (one for each specimen) are welded to a single support plate that is of a width that enables it to be introduced through the nozzle. However, this too cannot be inserted unless the equipment is out of service, although its introduction does not require removal of gas.

A slip-in rack (**Figure 27**) that is designed to be inserted and removed during the operation of the plant through a full-port gate valve attached to a nozzle of suitable diameter (3.8–5.1 cm) is described by Dillon *et al.*<sup>309</sup>. It consists of a short length of pipe flanged at one end to match the gate valve and has a backing-gland arrangement at the other. The coupons are mounted on a rod of small diameter welded to a long heavier rod. The valve is opened, and the support rod is pushed through the packing gland so that the specimen is introduced into the process stream. The specimens are removed by withdrawing the rod until they are again within the pipe section, the gate valve is closed, and the rack removed from the valve.

Access fittings that enable specimens to be introduced into plant that is operating at high pressures, but can also be used for ambient pressures are available. In some instances, it is possible to secure valuable information by substituting experimental materials for parts

**Figure 27** Slip-in corrosion test rack. Reproduced from Dillon, C. P.; Krisher, A. S.; Wissenburg, H. In: Ailor, W. H., Ed.; *Handbook on Corrosion Testing and Evaluation*; John Wiley, 1971.

of the operating equipment, a practice that is used most frequently with condenser tubes, evaporators or other heat exchangers or sections of piping systems.

The prediction of materials performance in plant conditions using modeling and corrosion test methods has been discussed by Strutt and Nichols.<sup>310</sup>

### 2.34.17.2 Specimens

A convenient size for a circular coupon is 3.8-cm diameter, a thickness of 0.32 cm, and a central hole of 1.1 cm. Although inherent in the philosophy of corrosion testing, the use of coupons with surfaces that simulate those in service has been found to be unsatisfactory owing to irreproducibility, and the standard procedure normally adopted is to abrade down to 120 grit. ASTM Method G4 gives details of preparation of specimens, evaluation of replicate exposures, and the application of statistical methods.

### 2.34.18 Atmospheric Tests

More or less standardized techniques have been developed for the exposure of specimens to atmospheric weathering. ASTM G 50 and ISO 8565 provide guidance on conducting atmospheric corrosion tests on metals, alloys, and metallic coatings. Procedures for recording data from atmospheric corrosion tests on metallic-coated steel specimens are given in ASTM G 33. The usual practice in the USA<sup>311</sup> is to mount bare specimens on racks that slope 30° from the horizontal and painted specimens on racks that slope 45° from the horizontal. The usual orientation is to have the specimens face south. In coastal exposures, it is not uncommon to have the specimens face the ocean. Steel specimens exposed vertically have been found to corrode about 25% more than similar specimens exposed at the 30° angle.<sup>312</sup> Vertical exposure was used in the large-scale tests of nonferrous metals undertaken by Subcommittee VI of ASTM Committee B-3.<sup>313</sup> Vertical exposure is also favored by Hudson.<sup>314</sup>

A typical test installation uses a frame to support racks on which the specimens are mounted by means of porcelain or plastics insulators. The insulators may be spaced to take specimens varying in size from 10.1 × 13.4 cm to 10.1 × 32 cm and even larger specimens may be used for certain tests. Special types of exposure have been devised to take into account important effects of partial shelter and accumulation of pools of water, as in the case of the specimen and method of support used by Pilling and Wesley<sup>315</sup> to compare steels for roofing.

Copson<sup>316</sup> has described in considerable detail the several factors that require attention in studying atmospheric corrosion, particularly of steels.

Several sizes and shapes of specimen have been used in addition to the common ones already mentioned. In the long-time test of bare and zinc-coated steels undertaken by ASTM Committee A-5 on Corrosion of Iron and Steel, full-size sheets were used.<sup>317</sup> This Committee has also exposed specimens in the form of hardware<sup>318</sup> and wire and fencing.<sup>319</sup>

The extent of deterioration may be measured by one or more of the following methods: visual examination, change in weight, or change in tensile properties. Visual inspection was depended primarily upon the A-5 tests of steel sheets.<sup>319</sup> Here, visible perforation more than 6 mm from an edge was the criterion of failure. This leaves much to be desired for close comparisons because of the frequency with which perforations may be obscured by heavy coats of rust.<sup>312</sup> Other shortcomings of the use of time to visible perforation as the criterion of corrosion resistance are as follows.

1. The removal of rust films or other corrosion products to facilitate inspection for perforation prior to termination of the exposure will change the natural performance of the material and is therefore not tolerable.
2. The recording of a perforation establishes only the time to failure and provides no idea of the progress of corrosion up to the point of failure.
3. The time to perforation may be influenced considerably by the random occurrence of pits that happen to meet after starting from opposite sides of a sheet. This chance meeting of pits may be determined only to a slight extent by the composition of the material and, therefore, will interfere with observations of the effects of composition.

Where changes in appearance are of paramount interest, as in the case of metallic and organic coatings on steel or other metals, visual examination is most desirable. To facilitate ratings on such a basis, photographic standards have been employed, for example, in tests on chromium-plated steel undertaken by ASTM Committee B-8 on Electrodeposited Metallic Coatings.<sup>320</sup> These ratings are supplemented by a shorthand description of the nature of the deterioration observed.

Similarly, photographic standards are recommended for rating organic coatings with respect to different modes of deterioration in ASTM D 610.

The most precise measurements of corrosion resistance require the use of specimens that can be

weighed accurately after careful removal of corrosion products by the techniques described earlier.

A sufficient number of specimens should be exposed initially to permit their withdrawal from test in appropriate groups, for example, 3 to 5 duplicates after at least three time intervals. For long-time tests, a suitable schedule would call for removals after 1, 2, 5, 10, and 20 years. (Editor's note: As with all weight loss tests, it is desirable to retain some specimens in an inert environment to provide a control for the evaluation of systematic errors (such as those due to changes in balance calibration).)

It is good practice to determine depths of pitting as well as mass loss.

As is the case with other types of corrosion testing, mass-loss determinations may fail to indicate the actual damage suffered by specimens that are attacked intergranularly or in such a manner as dezincification. In such cases, mechanical tests or microscopic examination will be required as discussed already in the section on evaluation techniques.

It is desirable for reporting of atmospheric corrosion tests to include a precise description of the climatic conditions that prevailed at the test site during the test so that the weather factors can be tied in with the results of exposure. Progress toward this aim has been made with the development of international standards that provide guidance on evaluating the corrosivity of atmospheric environments. Atmospheric corrosivity can be expressed in terms of environmental factors, the most important of which have to do with contaminants of the atmosphere and the time that the specimens are actually wetted by condensed moisture. In the case of organic coatings, the interacting effects of sunlight and moisture, and their sequence, complicate this problem even more.<sup>321</sup> Methods of measuring pollution (deposition rates of sulfur compounds and chlorides) are provided in ISO 9225. ISO 9223 defines five different categories of atmospheric corrosivity based on time of wetness and pollution. An alternative approach is to express atmospheric corrosivity in terms of the corrosion rate of standard materials, including carbon steel, weathering steel, zinc, copper, and brass. Methods of determining the corrosion rates for this purpose are given in ISO 9226, while ISO 9224 provides a classification of atmospheric corrosivity based on both the average and the steady-state corrosion rates of the standard metals.

Sereda<sup>322</sup> has described a method of determining time of wetness in which a strip of platinum foil ( $0.8 \times 7$  cm) is mounted on a zinc panel ( $10.1 \times 13.4$  cm) on both the skyward and groundward face.

Condensed moisture from dew, or rain or snow, results in a galvanic cell, the potential of which is monitored on a recorder, thus giving the time of wetness. Guttman and Sereda<sup>323</sup> found that if the  $\text{SO}_2$  content remained essentially constant, the corrosion rate of zinc was related to time of wetness; furthermore, the dew detector registered the presence of moisture on the panel when the relative humidity ranged between 82% and 89%, thus providing a means of estimating from long-term weather data, such as temperature and relative humidity, the time a specimen is likely to be wet.

## 2.34.19 Atmospheric Galvanic Tests

Studies of galvanic corrosion in the atmosphere are experimentally simpler than those conducted in solution in the laboratory. The environment is taken as it comes, and the relatively high electrical resistance of the rain and moisture films that serve as electrolytes restricts the distance through which the galvanic action can extend and thus limits the relative area effects that complicate galvanic corrosion in solutions of high conductivity. Standard test methods for assessing galvanic corrosion caused by the atmosphere are given in ASTM G 104 and in ISO 7441.

Because of the limited proportion of the areas of a couple that actually participates in the galvanic action, it is difficult to make quantitative measurements that separate the galvanic action from the total effects of exposure. Thus, many of the observations are likely to be qualitative ones, and often no more than what can be determined by visual inspection or measurements of changes in strength, etc. as a result of any localized galvanic action.

An idea of the distribution of galvanic corrosion in the atmosphere is provided by the location of the corrosion of magnesium exposed in intimate contact with steel in the assembly shown in [Figure 28](#) after exposure in the salt atmosphere 25 m from the ocean at Kure Beach, North Carolina, for 9 years. Except where ledges or crevices may serve to trap unusual amounts of electrolyte, it may be assumed that, even with the most incompatible metals, simple galvanic effects will not extend more than about 4–5 mm from the line of contact of the metals in the couple.

The extent of galvanic action in atmospheric exposure may also be restricted by the development of corrosion products of high electrical resistance between the contacting surfaces: this is especially likely to occur if one of the metals in the couple is an iron or steel that will rust. In long-time tests, such

possible interruptions in the galvanic circuit should be checked by resistance measurements from time to time so as to determine the actual periods in which galvanic effects could operate.

**Figure 28** Distribution of galvanic effects around contact of a magnesium casting and a steel core.

The test assembly used originally by Subcommittee VIII of ASTM Committee B-3 in its comprehensive studies of atmospheric galvanic corrosion<sup>324</sup> had the disadvantage that it depended on paint coatings to confine corrosion to the surfaces in actual contact with each other. In interpreting the results, it was frequently difficult to decide how much corrosion was due to galvanic action and how much to a variable amount of normal corrosion through failure of the paint system.

These difficulties were overcome in a design developed by Subcommittee VIII of ASTM Committee B-3<sup>325</sup> (**Figure 29**). In this assembly, each of the two middle specimens has a specimen of the other metal each side of it, and only these middle specimens are considered in appraising the results.

A fairly direct way of observing galvanic effects, which also permits changes in mechanical properties to be measured, involves the preparation of a composite specimen formed by attaching a strip, or strips, of one metal to a panel of another one. Tensile test specimens that include the areas of galvanic action can be cut from these panels after exposure, as shown in **Figure 30**.

A modification of the specimen shown in **Figure 30** may be made simply by lapping a panel of one material over a panel of another one. The greatest effects may

**Figure 29** Atmospheric galvanic couple test assembly.

**Figure 30** Plate and fastening type galvanic couple test specimen.

be observed when such panels are exposed with the laps facing up so as to favor retention of corrosive liquids along the line of contact. To permit observations of secondary effects of corrosion products, or exhaustion of corrosive constituents, the relative positions of the dissimilar metals should be changed from top to bottom in duplicate test assemblies.

Where the practical interest is in possible galvanic effects of fastenings, it is simple to make up specimens to include such couple assemblies as illustrated in [Figure 31](#).

A type of assembly calculated to favor maximum galvanic action was developed by the Bell Telephone Laboratories and is illustrated in [Figure 32](#). Here, the less noble metal is in the form of a wire wound in the grooves of a threaded specimen of the metal believed to be more noble. Good electrical contact is achieved by means of set screws covered with a protective coating. This assembly favors accumulation of corrosive liquids around the wire in the thread grooves. Corrosive damage is also favored by the high ratio of surface to mass in the wire specimens.

To determine whether a protective metallic coating will retard or accelerate corrosion of a basis metal, and to what distance either effect will extend, specimens in which strips of various widths are left bare or made bare have been used by Subcommittee 11 of ASTM Committee B-8.<sup>325</sup> The extent of corrosion in and near the bare strips as compared with that on a completely bare or completely coated specimen will provide a measure of the extent of galvanic action and the distance through which the effect is able to extend from the edges of the bare strips.

### 2.34.20 Tests in Natural Waters

The corrosion testing of metals in natural waters is usually conducted in field or service tests since the

conditions of flow are important and often rate-determining. Testing will be concerned with mains water (potable water), river-water and seawater, or combinations of these as in estuarine conditions. Test specimens of various geometries will be used, for example, in the form of wires, plates, tubes, etc., and certain general precautions should be followed.

1. The specimens should be mounted so that they are insulated from their supporting racks and from each other. Such insulation can be achieved by the use of fastening assemblies, such as those illustrated in [Figure 33](#). Occasional difficulties have been encountered with this sort of assembly for tests of copper and high-copper alloys because of deposition of copper from corrosion products along the surfaces of the insulating tubes, which provided a metallic bridge between the specimens and the rack and introduced undesired galvanic effects. The required insulation and support can be provided by use of porcelain or plastic knob insulators in much the same manner as used on atmospheric test racks. A modified design has the advantage of offering less resistance to the flow of water and is less likely to serve as a form of screen to catch debris floating on, or suspended in, the water. Additional details of rack design may be found in the section on seawater tests in *The Corrosion Handbook* (Uhlig, Selective Bibliography).
2. In the case of corrosion tests in the sea or in other large volumes of water, that is, as opposed to tests in waters flowing within pipes, all the specimens to be compared should be suspended at the same depth or should pass through the same range of depths. Isolated specimens exposed at different depths will not be corroded in the same way as continuous specimens that extend through the total range of depth to be studied. This is especially the case with specimens exposed to seawater

**Figure 31** Specimen for studying galvanic corrosion resulting from fasteners.

**Figure 32** Bolt and wire type atmospheric galvanic couple test specimen.

**Figure 33** Scheme for insulating specimens from metal test racks.

from above high tide to below low tide. Where the behavior of structures, such as piling, that pass through these zones is to be investigated, the test specimens must be continuous and large enough to extend through the total range in order to take into account differential aeration and other possible concentration cells that may have such a tremendous effect on the results secured.<sup>326</sup> For example, in seawater exposure, isolated specimens of steel exposed in the tidal zone have corroded 10 times as fast as portions of continuous specimens of the same steel in the same zone that extended also below low-tide level.<sup>312</sup>

3. The specimens should be oriented so that their flat surfaces are parallel to the direction of water flow and so that one specimen will neither shield an adjacent specimen from effects of water velocity nor create any considerable extra turbulence upstream of it.
4. In tests in seawater where accumulations of marine organisms are likely, specimens exposed parallel to each other should be spaced far enough apart to ensure that the space between specimens will not become completely clogged by fouling organisms. A minimum spacing of 100 mm is suggested.
5. Wooden racks used in seawater tests are likely to be subject to severe damage by marine borers. The wood used, therefore, must be treated with an effective preservative, for example, creosote applied under pressure, if the test is to extend for several years. Organic copper compound preservatives may suffice for shorter tests, for example, 2 or 3 years. Since the leaching of such preservatives may have some effects on corrosion, metal racks fitted with porcelain or plastic insulators have an advantage over wooden racks.
6. Where constant depth of immersion is desired in spite of tidal action, it is necessary to support the test racks from a float or raft.

Recommended methods for assessing the corrosivity of waters, including flowing potable waters, are described in ASTM D 2688. Three procedures are described in which test specimens in the form of wires, sheets, or tubes are placed in pipes, tanks, or other equipment. The test assembly for the first of these consists of three helical wire coils mounted in series on, and electrically insulated from, a supporting frame. The assembly must be installed so that flow is not disturbed and turbulence and high velocities, for example, of more than  $1.53 \text{ m s}^{-1}$ , are avoided. A minimum test period of 30 days is recommended. Procedures for the other specimen forms are given in the standard.

An extensive study of the corrosion of metals in tropical environments has been carried out by Southwell.<sup>327</sup> Tests have included atmospheric exposure, and exposure in seawater under mean tide and fully immersed conditions for a range of ferrous and non-ferrous metals and alloys.

The Marine Corrosion Working Party of the European Federation of Corrosion has published valuable advice on corrosion testing in service.<sup>328</sup>

### 2.34.21 Field Tests in Soil

The precautions generally applicable to the preparation, exposure, cleaning, and assessment of metal test specimens in tests in other environments will also apply in the case of field tests in the soil, but there will be additional precautions because of the nature of this environment. In the case of aqueous, particularly seawater, and atmospheric environment, the physical and chemical characteristics will be reasonably constant over distances covering individual test sites, whereas this will not necessarily be the case in soils, which will almost inevitably be of a less homogeneous nature. The principal factors responsible for the corrosive nature of soils are the presence of bacteria, the chemistry (pH and salt content), the redox potential, electrical resistance, stray currents, and the formation of concentration cells. Several of these factors are interrelated.

These considerations will significantly affect the location of test specimens in field testing. It is clearly important to ensure that the conditions of exposure are accurately known so that the corrosion test results may be interpreted with respect to the end-use requirements.

Two civil engineering operations require particular attention when soil corrosion tests in the field are

required. These are (1) the use of reinforced earth structures in which the corrosion conditions will differ from those at the site from which the soil has been taken and which may take some time to come to equilibrium in the new site, and (2) the use of reclaimed or contaminated land where unusual corrosive agents may be present in irregular distribution. In both these situations, considerable thought should be given to the corrosion test procedures.

Soil burial tests are popular despite the precautions that are needed. It is also important that a sufficient number of specimens are exposed so that statistical treatment of the results may be applied to compensate for some of the inevitable variations in the exposure conditions. Certain precautions originally set out in 1937<sup>329</sup> are still valid, and are as follows:

1. A sufficient number of specimens to yield a reliable coverage should be included.
2. The test site should be typical of the type of soil to be investigated.
3. The depth of burial should be that which will be occupied by the structure of interest. Specimens to be compared should be buried at the same depth. Ideally, tests for structures, such as piling, that will extend through several horizons would require the use of test specimens long enough to extend to the same depth.
4. Specimens should be separate so that they will not affect the corrosion of each other. A minimum spacing of two diameters was proposed.
5. Cylindrical specimens should be laid horizontally.
6. Sheet or plate specimens should be placed on edge.
7. The ends of pipe specimens should be closed to prevent internal corrosion.
8. Sufficient specimens should be provided to allow withdrawals after several time intervals so as to permit observations of changes in corrosion rates with time.
9. A portion of the original surface should be protected so as to provide a datum line for the measurement of pit depths.
10. In applying results of tests on small specimens to estimating corrosion, particularly by pitting on large structures, the effect of the increased area in increasing the depth of pitting must be taken into account.<sup>330</sup>

#### **2.34.21.1 Other Tests**

Other tests to determine bacterial—notably sulfate reducing—activity, soil resistivity, pH, redox potential,

etc. will provide valuable data to supplement the results obtained with test specimens. A useful account of some of these was given in.<sup>331</sup> A scheme for assessment of corrosivity of soils based on some of these parameters has been given by Tiller.<sup>332</sup>

A number of standards exist for the determination of some of these parameters. BS 1377: Part 3 refers to methods of tests for soils for civil engineering purposes, and Part 9 refers to these and corrosivity tests in situ. It is significant that the standard draws attention to the fact that the results of the tests that are described should be interpreted by a specialist. ASTM tests for pH and resistivity of soil used for corrosion testing are covered by G51 and G57, respectively.

#### **2.34.22 Corrosion Testing of Organic Coatings**

Programs to evaluate the corrosion protection by organic coatings on metals are intended to establish relationships between coating properties and performance. Such knowledge is essential to the most effective use of organic coating systems in corrosion control. Depending on the detail with which such studies are performed, light may be shed on the mechanism of coating deterioration as well.

If valid and useful relationships are to be established, it is essential that the factors affecting performance be recognized and form part of the test record. Since the performance is determined by interactions between the coating, the substrate and the surrounding environment against which protection is sought, significant factors and their interrelationships will vary with the nature of the service.

Care in designing and conducting the test in no way reduces the need for discrimination on the part of the person using the test data in the selection of a coating for a particular purpose. Test environments must reflect the deteriorating influences of the service for which they are applicable. A coating system cannot reliably be selected for service in a chemical plant on the basis of performance determined in a rural atmosphere.

Thus, both the proper conduct of the testing program and the valid use of the data depend on an understanding of the nature of organic coatings and of the forces through which they are degraded.

#### **2.34.22.1 Behavior of Organic Coatings**

An organic coating provides corrosion protection through the interposition of a continuous, adherent,

high-resistance film between the metal surface and its environment. In principle, its function is the mechanical exclusion of the environment from the metal surface. It seldom, if ever, succeeds practically in achieving this since all continuous organic films are permeable to some degree to moisture, and many coatings either have occasional physical defects or acquire them in service. Surface conversion treatments, such as phosphate and chromate dips, are used to supplement the physical protective properties of coatings, as are chemically inhibiting primers and wash primers. When such treatments are used, they must be included in the record as constituting a part of the coating system.

Critical parts of the test program are the preparation of test specimens, the selection of the exposure conditions (both in laboratory and field tests), and the selection of significant coating properties to be evaluated as a measure of deterioration with time.

### 2.34.22.2 Preparation

Specimens will normally be flat panels, large enough to avoid any effects caused by nearby edges of the specimen. Edges and backs are usually coated unless the effect of uncoated edges is an intended test variable. Panels may include the structural features of plates, channels, welds, sharp edges, pits, or depressions, depending on the service for which the data are to be applicable.

The composition of the basis metal has been found to influence the performance of organic finishes in many cases. Thus, composition is a significant test variable and must be considered in comparing test data.

It is particularly important that surface roughness and cleanness, which greatly affect adhesion, should be carefully controlled and that the procedures used to achieve them be a part of the test record. A high degree of cleanliness is normally sought. If, however, the data are to be applicable to the painting of outdoor structures, a certain amount of outdoor weathering becomes a part of the specimen preparation prior to coating. Specimens again will be of the basis metal appropriate for the related service application.

The thickness of a coating plays an important part in determining its physical characteristics. Uniformity of thickness among specimens is therefore necessary, particularly when coating deterioration is to be assessed by changes in such properties. For the preparation of reproducible specimens, methods of

applying coatings in uniform thicknesses are available, as are methods for accurately measuring film thickness.

### 2.34.22.3 Exposure Conditions

In considering exposure tests, whether in the form of laboratory, field, or service tests, it is important to consider the purpose of the test and the relevance of the data to the anticorrosion function of the coating. Thus, in the case of paint coatings, factors such as gloss deterioration, chalking, and color retention are of considerable importance in some industries, for example, the automotive industry, but perhaps of minor importance in the painting of structural steelwork. These assessment factors can nevertheless be of significance, since they may be the precursors of corrosion of the basis metal.

#### 2.34.22.3.1 Laboratory tests

Laboratory tests are often conducted with the purpose of providing an accelerated test procedure and if intelligently used, that is, with proper respect for their limitations, they are of value in determining the probable order of durability, and hence, by implication, corrosion protection of a group of paints. They can also be of value in assessing the quality of a range of similar compositions where there is already some knowledge of the performance of the general composition. Although continuing attention is given to the correlation of accelerated tests with field trials and service performance, caution must always be exercised in attempting to predict the type of failure likely to occur under conditions of natural exposure. Certainly, an approach based on 'the rougher the treatment, the better the test' cannot be justified. Three main classes of laboratory test can be identified and may be conveniently classified under the headings of (1) electrochemical, (2) coating adherence, and (3) exposure cabinets – including weatherometers.

#### *Electrochemical tests*

This group includes the various electrochemical tests that have been proposed and used over the last fifty years or so. These tests include a number of techniques ranging from the measurement of potential–time curves, electrical resistance, and capacitance to the more complex electrochemical impedance methods. The various methods have been reviewed by Walter.<sup>333</sup> As the complexity of the technique increases, that is, in the mentioned order, the data

that are produced will provide more types of information for the metal-paint system. Thus, the impedance techniques can provide information on the water uptake, barrier action, damaged area, and delamination of the coating as well as the corrosion rate and corroded area of the metal. However, it must be emphasized that the more comprehensive the technique, the greater the difficulties that will arise in interpretation and in reproducibility.

#### **Adherence tests**

This group of techniques involves the testing of the metal-to-paint adherence. These techniques are covered by descriptions such as cohesion,<sup>334</sup> blister,<sup>335</sup> pull off (BS EN 24624), and cross-cut (BS EN ISO 2409). Detailed descriptions of these techniques will be found in the appropriate references.

#### **Exposure cabinets**

This group of laboratory tests include the so-called exposure cabinets, salt-spray, and weatherometer tests in which the paint-coated panels are subjected to various cycles of wetting and exposure to ultraviolet light to simulate atmospheric conditions of exposure. BS 3900: Part F3 describes a weatherometer consisting of a 1.2 m diameter drum that rotates at 1 rev/20 min, and has facilities for spraying the panels (100 × 150 mm) periodically during a 24 h cycle and exposing them to ultraviolet light by means of an enclosed carbon arc. Spraying with distilled water is effected by means of an atomizer and fan using the following 24-h cycle: 4 h off, 2 h on, 10 h off, 2 h on and 1 h off; the final 1 h is used for checking the arc. The test is continued for 7 days, at the end of which the panels are examined visually for change of color, loss of gloss and blistering, and for checking, cracking, and chalking by means of a lens (×25).

An appraisal of artificial weathering methods was given in a report by Hoey and Hipwood<sup>336</sup> who described the effectiveness of various weatherometer tests such as those described in BS 3900: Part F3 and ASTM G 152/52. Although these tests simulate atmospheric exposure, it is not possible to obtain a direct correlation owing to variation in outdoor exposure conditions from place to place, but they serve a very useful purpose in providing a preliminary sorting of paints that can then be tested in the field.

#### **2.34.22.3.2 Field and plant tests**

Field exposure of test panels offers the benefit of a high degree of control over surface preparation and application. Moreover, through standardized

exposure conditions, broader comparisons between both paint systems and locations are possible. More importantly, since replicates may be removed and laboratory tested periodically, changes in properties can be followed in considerable detail. At least four replicates should be examined for each exposure period to minimize the effects of atypical specimens.

The exposure site is selected according to the service for which the data are to be applicable. For atmospheric service, such factors as marine and industrial contaminants, sunlight, dew, and sand abrasion must be considered. Atmospheric specimens are normally mounted at 45°, facing south. This has been shown to provide about a 2:1 acceleration of failure compared with a vertical exposure. Whether this or other standardized positions are used, the details of the exposure are an important part of the test record.

The degree of deterioration experienced over a given test period varies with climatic conditions. Since these differ significantly from one season to another, a standard specimen, the performance of which is well known, should be included with each exposure to increase the validity of coating comparisons.

For other environments, such as in seawater or in chemical plants, exposure conditions that most nearly duplicate those of the related service, and are at the same time reproducible, are used. Impingement by water or water carrying entrained solids, thermal effects, and physical abuse are among the factors to be considered.

#### **2.34.22.4 Coating Evaluation**

The performance of organic finishes on test is evaluated by visual observation and by physical tests made upon coated specimens that have been exposed for various periods of time to natural or accelerated weathering conditions. Electrical tests are sometimes used on immersed specimens.

Inspection of test panels at the test sites consists of visual observations of blistering (see ASTM D 714) and the appearance of rust (see ASTM D 610). For these, photographs showing various degrees of degradation that serve as observational standards greatly reduce variations between observers. Results of consecutive observations entered on charts provide visual records of the trend of these features with time.

These more serious evidences of degradation, however, are preceded by invisible physical alterations within the coatings, which can be detected readily and quantitatively by suitable physical tests of replicate specimens removed from tests at periodic

intervals. The use of such tests to reveal incipient coating changes is, in a sense, a means of accelerating the test program without distortion of the test environment. This approach is especially dependent on uniformity of properties among replicates, hence on reproducible application techniques. Moreover, since many coating properties are highly sensitive to changes in temperature and relative humidity, equilibrium of the specimens during testing is necessary. Testing conditions are commonly 25 °C and 50% RH.

Physical tests appropriate for this type of evaluation are not necessarily limited to those properties that the coating may be called upon to display in service. A coating that shows a decrease in distensibility from 20% to 10% is still quite capable of withstanding the expansion and contraction of the substrate in atmospheric temperature cycling, yet such a coating can be expected to fail in service earlier than one that shows no decrease. Thus, the properties of value are those that have been established as reliable indices of deterioration.

Besides providing early comparative data on coating performance, physical tests in dealing with intrinsic coating properties provide much-needed quantitative information on the relationships between the several factors affecting the ageing of organic films. The tests cited as follows are those that have been shown to indicate reliably significant changes in the condition of coatings on tests.

#### **2.34.22.4.1 Distensibility**

This property is very sensitive to chemical changes within the coating. Its measurement thus shows the beginning of normal ageing or of deterioration through reaction with the environment. Distensibility is generally determined by bending the test panels over a conical mandrel of known radius and calculating the % elongation at first rupture.

#### **2.34.22.4.2 Abrasion tests**

In these tests, the end point is normally taken as the amount of abrasion required to penetrate the coating. The results thus reflect the strength of the coating, its cohesion, and in some cases, its adhesion to the basis metal as well as resistance to abrasion.

#### **2.34.22.4.3 Hardness**

Coating hardness is related to the method of measurement. Results reflect the resistance to scratching as well as to indentation.

#### **2.34.22.4.4 Impact tests**

Such tests reveal the resistance of coatings to deformation and destruction by concentrated sudden stresses. They thus throw considerable light on the integrity of the metal-coating bond. Changes in adhesion through chemical reaction at the paint/metal interface will be reflected in the impact-test values.

These tests for characterizing coating properties necessarily continue to involve a certain amount of empiricism. The intelligent use of these tests, however, has shown that wide variations of physical and electrochemical characteristics of coatings as a function of composition may be obtained, and further, that significant changes in these characteristics, that can be measured before the usual evidence of failure appears, occur upon natural and accelerated ageing.

### **2.34.23 Test Methods for Corrosion Inhibitors**

#### **2.34.23.1 Immersed Conditions**

Since corrosion inhibitors are used in a wide range of applications, no universal test method exists. Recognized methods tend to relate to a product or process in which the inhibitor forms a part rather than to the inhibitor *per se*. Thus, tests exist for inhibited coolants, cooling waters, cutting oils, pickling liquids, etc.

The considerations applicable to corrosion test methods also apply to tests for inhibited products. The metals and alloys used, their surface preparation, the temperature, flow rate, composition of the test medium, the presence of heat transfer, and so on must all be relevant to the proposed use of the inhibited product. As with other test methods, there are those tests that have been developed in particular laboratories for the development of inhibitors for particular purposes and those that have acquired national or international recognition by appropriate standards-writing bodies.

The three types of test procedure discussed in this chapter may often be identified in testing of inhibitors or inhibited products. The testing of inhibited engine coolants provides a suitable example.

Laboratory tests used in the development of inhibitors can be of various types and are often associated with a particular laboratory. Thus, in one case, simple test specimens, either alone or as bimetallic couples, are immersed in inhibited solutions in a relatively simple apparatus, as illustrated in [Figure 34](#). Sometimes, the test may involve heat transfer, and a simple test arrangement is shown in [Figure 35](#). Tests of

**Figure 34** Experimental arrangements for corrosion tests without heat transfer. (a) Test vessel and specimen, (b) assembly for single or bimetallic specimens, and (c) assembly for brass/solder/brass specimens.

**Figure 35** Apparatus for testing inhibitors with metal-to-coolant heat transfer.

these types have been described in the literature.<sup>337,338</sup> However, national standards also exist for this type of test approach. BSI and ASTM documents describe laboratory test procedures and, in some cases, provide recommended pass or fail criteria (BS

5117: Part 2: Section 2.2; BS 6580; ASTM D 1384). Laboratory testing may involve a recirculating rig test in which the intention is to assess the performance of an inhibited coolant in the simulated flow conditions of an engine cooling system. Although test procedures have been developed (BS 5117: Part 2: Section 2.3, ASTM D 2570), problems of reproducibility and repeatability exist, and it is difficult to quote numerical pass or fail criteria.

These laboratory tests may be followed by engine dynamometer tests (BS5117: Section 2.4) and finally by road tests in working vehicles (BS 5117: Part 2: Section 2.5), thus completing the sequence of laboratory, field, service testing.

The problems that have been experienced in the recirculating rig test are indicative of those often met in performance testing. Attempts to reproduce the service conditions in a laboratory test inevitably involve attempting to reproduce each of the controlling conditions that exist in the real situation. Variations, which may be relatively small, in these simulations can lead to significant differences in test results. There is therefore much to be said for keeping test conditions as simple as possible rather than attempting to reproduce accurately the conditions in practice. A balance between reproducibility and realism has to be struck.

The testing of inhibitors for use in oil and gas production, transport, and processing normally involves two-phase oil–water fluids with, sometimes, a solid

phase, for example, entrained sand particles. Tests are usually of the dynamic variety with continuous movement so that test specimens contact all phases present. A well known laboratory test procedure is the so-called wheel test in which bottles of about 200-cm<sup>3</sup> volume containing weighed test specimens and a two-phase fluid saturated with an appropriate gas (CO<sub>2</sub> or H<sub>2</sub>S) rotate inside a temperature-controlled chamber.<sup>339</sup> For many applications in these technologies, data are required for high temperature high-pressure conditions, and the use of autoclaves then becomes essential.<sup>340</sup> Two reviews on test procedures for corrosion inhibitors have been published.<sup>341,342</sup>

### 2.34.23.2 Vapor Phase Conditions

The testing of vapor phase inhibitors, usually referred to as volatile corrosion inhibitors, is essentially a matter of placing a test specimen in the vapor space of a closed vessel containing an aggressive atmosphere – frequently water vapor, perhaps with SO<sub>2</sub> present – and a quantity of the inhibitor. Variations on the basic technique include provision for circulation of the vapor, the use of paper impregnated with inhibitor, provision for temperature cycling, etc.

In the early 1950s, Wachter *et al.*,<sup>343</sup> in the USA, described a humidity cabinet test in which metal specimens were supported inside inverted glass tubes containing a slip of inhibitor-impregnated paper in the lower end. The test was conducted at 37.7 °C and 100% RH. In the UK, Stroud and Vernon<sup>344</sup> described two types of test: (1) with a single test specimen suspended from a cork in the neck of a 250-cm<sup>3</sup> conical flask containing 25 cm<sup>3</sup> of water with 5 mass% of the inhibitor, which was held at 35 °C during the day and at room temperature overnight; and (2) with specimens suspended in the upper part of glass tubes containing water and inhibitor with the lower part of the tubes immersed in a thermostatted bath so that condensation occurred in the upper part of the tubes. Other forms of test using a climatic cabinet with tropical or industrial atmospheres have also been described.<sup>345</sup>

Acknowledgements are made to Dr. R. Francis, Dr. T. G. Gooch, Prof. J. S. Llewelyn Leach, Dr. T. C. Lindley, Mr. G. O. Lloyd, Dr. D. Mills, Mr. T. E. Such, Mr. A. K. Tiller, and Mr. P. J. Trant for their helpful comments in connection with the updating of this section, which is based on the original by Dr. L. L. Shreir and Dr. F. L. LaQue.

## Appendix A: Methods of Removal of Corrosion Product

This appendix provides information on chemical and electrochemical treatments, which have been recommended for the removal of corrosion products. In using these methods the following points need to be borne in mind:

1. The duration of chemical or electrochemical treatment should be kept to the minimum necessary to remove the corrosion product. Loosely adherent material should be removed beforehand by suitable mechanical means, for example, scrubbing.
2. The combined action of chemical (or electrochemical) treatment and scrubbing is often more effective than either method alone. It is frequently advantageous to alternate short periods of immersion with scrubbing to remove any corrosion product that has become loosened by the action of the chemical reagent.
3. The rate of attack of the chemical reagent on sound metal should be determined on a separate uncorroded sample of the material being cleaned, and if necessary a correction should be applied to the loss in weight of the corroded specimen. However, where a metal, and particularly an alloy, is heavily corroded, thus exposing a surface structure different from that of an uncorroded surface, it will be necessary to check the reliability of the cleaning method (Mercer, A. D.; Butler, G.; Warren, G. M. *Br. Corrosion J.* **1977**, *12*(2), 122–126). A procedure for obtaining more accurate weight loss data in these circumstances has been described [ISO 8407].
4. The possibility of redeposition of metal from the dissolved corrosion product or, if electrochemical treatment is employed, from the anode material should always be kept in mind. If there is reason to believe this has occurred during removal of the corrosion product, further treatment to remove the redeposited metal will be necessary before the weight loss due to corrosion is measured.

### A.1 Procedures for Removing Corrosion Products

The removal of corrosion products from metal specimens is described in Reference 1 and in ASTM G 1 and ISO 8407 and certain of these procedures are described as follows.

**A.1.1 Electrolytic cathodic cleaning**

After scrubbing to remove loosely attached corrosion products, cathodically polarize in hot dilute sulfuric acid under the following conditions:

Electrolyte-sulfuric acid (5 wt. %) plus an inhibitor ( $0.5 \text{ kg m}^{-3}$ ) such as diorthotolyl thiourea, quinoline ethiodide, or  $\beta$ -naphthol quinoline. The temperature should be  $75^\circ\text{C}$ , the cathode current density  $2000 \text{ Am}^{-2}$ , and the time of cathodic polarization 3 min. The anode should be carbon or lead. If lead anodes are used, lead may deposit on the specimens and cause an error in the weight loss. If the specimen is resistant to nitric acid the lead may be removed by a flash dip in 1:1 nitric acid. Except for this possible source of error, lead is preferred as an anode, as it gives more efficient corrosion product removal.

After the electrolytic treatment, scrub the specimen with a brush, rinse thoroughly and dry.

Electric treatment may result in the redeposition of a metal, such as copper, from reducible corrosion products and thus decrease the apparent weight loss.

**A.1.2 Chemical Cleaning****A.1.2.1 Copper and nickel alloys**

Dip for 1–3 min in 1:1 HCl or 1:10  $\text{H}_2\text{SO}_4$  at room temperature. Scrub lightly with bristle brush under running water, using fine scouring powder if needed.

**A.1.2.2 Aluminum alloys**

Dip for 5–10 min in an aqueous solution containing 2 wt. % chromic acid ( $\text{CrO}_3$ ) plus 5 vol. % orthophosphoric acid ( $\text{H}_3\text{PO}_4$ , 85%) maintained at  $80^\circ\text{C}$ . Ultrasonic agitation will facilitate this procedure.

Rinse in water to remove the acid, brush very lightly with a soft bristle brush to remove any loose film, and rinse again. If film remains, immerse for 1 min in concentrated nitric acid and repeat previous steps. Nitric acid may be used alone if there are no deposits. (See comments on this method when used for corroded specimens in the paper by Mercer, A. D.; Butler, G.; Warren, G. M. *Br. Corrosion J.* 1977, 12, 122.)

**A.1.2.3 Tin alloys**

Dip for 10 min in boiling trisodium phosphate solution (15%). Scrub lightly with a bristle brush under running water, and dry.

**A.1.2.4 Lead alloys**

Preferably use the electrolytic cleaning procedure just described. Alternatively, immerse for 5 min in boiling 1% acetic acid. Rinse in water to remove the acid and brush very gently with a soft bristle brush to remove any loosened matter.

Alternatively, immerse for 5 min in hot 5% ammonium acetate solution, rinse and scrub lightly. This removes  $\text{PbO}$  and  $\text{PbSO}_4$ .

**A.1.2.5 Zinc**

Immerse the specimens in warm ( $60$ – $80^\circ\text{C}$ ) 10%  $\text{NH}_4\text{Cl}$  for several minutes. Then rinse in water and scrub with a soft brush. Then immerse the specimens for 15–20 s in a boiling solution containing 5% chromic acid and 1% silver nitrate. Rinse in hot water and dry.

Note: in making up the chromic acid solution it is advisable to dissolve the silver nitrate separately and add it to the boiling chromic acid to prevent excessive crystallization of the silver chromate. The chromic acid must be free from sulfate to avoid attack on the zinc. Immerse each specimen for 15 s in a 6% solution of hydriodic acid at room temperature to remove the remaining corrosion products. Immediately after immersion in the acid bath, wash the samples first in tap water and then in absolute methanol, and dry in air. This procedure removes a little of the zinc and a correction may be necessary.

**A.1.2.6 Magnesium alloys**

Dip for approximately 1 min in boiling 15% chromic acid to which 1% silver chromate solution has been added with agitation.

**A.1.2.7 Iron and steel**

Preferably use the electrolytic cleaning procedure, or else immerse in Clark's solution (hydrochloric acid 100 parts, antimonious oxide 2 parts, stannous chloride 5 parts) for up to 25 min. The solution may be cold but it should be vigorously stirred. Remove scales formed under oxidizing conditions on steel in 15 vol. % concentrated phosphoric acid containing 0.15 vol. % of an organic inhibitor at room temperature.

**A.1.2.8 Stainless steels**

Clean stainless steels in 20% nitric acid at  $60^\circ\text{C}$  for 20 min. In place of chemical cleaning, use a brass scraper

or brass bristle brush or both, followed by scrubbing with a wet bristle brush and fine scouring powder.

Other methods of cleaning iron and steel include immersion in molten sodium hydride and cathodic treatment in molten caustic soda. These methods may be hazardous to personnel, and should not be carried out by the uninitiated, or without professional supervision.

### A.1.3 General Note

Whatever cleaning method is used, the possibility of removal of solid metal is present. This will result in error in the determination of the corrosion rate. One or more cleaned and weighed specimens should be recleaned by the same method and reweighed. Loss due to this second treatment may be used as a correction to that indicated by the first weighing.

## Appendix B: Standards

### B.1 ISO Standards

ISO standards are managed by the International Organization for Standardization, known as ISO for short (the short name is taken from the Greek 'iso' meaning equal, rather than being an abbreviation of the name of the organization, which would, of course be different in different languages). ISO standards have a simple naming convention, ISO nnnn-pp:yyyy, where nnnn is the standard number, pp the optional part number and yyyy the year of publication. For standards published in collaboration with national bodies, ISO may be supplemented with the abbreviation of the body (as in ISO/ASTM ...). In the main text we have just given the standard number and part number; here we list the current version at the time of writing.

ISO 1456:2003 Metallic coatings – Electrodeposited coatings of nickel plus chromium and of copper plus nickel plus chromium

ISO 2160:1998 Petroleum products – Corrosiveness to copper – Copper strip test

ISO 2810:2004 Paints and varnishes – Natural weathering of coatings – Exposure and assessment

ISO 3651-1:1998 Determination of resistance to intergranular corrosion of stainless steels – Part 1: Austenitic and ferritic-austenitic (duplex) stainless steels – Corrosion test in nitric acid medium by measurement of loss in mass (Huey test)

ISO 3651-2:1998 Determination of resistance to intergranular corrosion of stainless steels – Part 2: Ferritic, austenitic and ferritic-austenitic (duplex) stainless steels – Corrosion test in media containing sulfuric acid

ISO 4536:1985 Metallic and nonorganic coatings on metallic substrates – Saline droplets corrosion test (SD test)

ISO 4538:1978 Metallic coatings – Thioacetamide corrosion test (TAA test)

ISO 4539:1980 Electrodeposited chromium coatings – Electrolytic corrosion testing (EC test)

ISO 4541:1978 Metallic and other nonorganic coatings – Corrodokote corrosion test (CORR test)

ISO 4543:1981 Metallic and other nonorganic coatings – General rules for corrosion tests applicable for storage conditions

ISO 4623-1:2000 Paints and varnishes – Determination of resistance to filiform corrosion – Part 1: Steel substrates

ISO 4623-2:2003 Paints and varnishes – Determination of resistance to filiform corrosion – Part 2: Aluminum substrates

ISO 6251:1996 Liquefied petroleum gases – Corrosiveness to copper – Copper strip test

ISO 6314:1980 Road vehicles – Brake linings – Resistance to water, saline solution, oil and brake fluid – Test procedure

ISO 6315:1980 Road vehicles – Brake linings – Seizure to ferrous mating surface due to corrosion – Test procedure

ISO 6505:2005 Rubber, vulcanized or thermoplastic – Determination of tendency to adhere to and corrode metals

ISO 6509:1981 Corrosion of metals and alloys – Determination of dezincification resistance of brass

ISO 6988:1985 Metallic and other nonorganic coatings – Sulfur dioxide test with general condensation of moisture

ISO 7120:1987 Petroleum products and lubricants – Petroleum oils and other fluids – Determination of rust-preventing characteristics in the presence of water

ISO 7384:1986 Corrosion tests in artificial atmosphere – General requirements

ISO 7441:1984 Corrosion of metals and alloys – Determination of bimetallic corrosion in outdoor exposure corrosion tests

ISO 7539-1:1987 Corrosion of metals and alloys – Stress corrosion testing,

Part 1: General guidance on testing procedures  
ISO 7539-2:1989 Corrosion of metals and alloys – Stress corrosion testing,  
Part 2: Preparation and use of bent-beam specimens  
ISO 7539-3:1989 Corrosion of metals and alloys – Stress corrosion testing,  
Part 3: Preparation and use of U-bend specimens  
ISO 7539-4:1989 Corrosion of metals and alloys – Stress corrosion testing,  
Part 4: Preparation and use of uniaxially loaded tension specimens  
ISO 7539-5:1989 Corrosion of metals and alloys – Stress corrosion testing,  
Part 5: Preparation and use of C-ring specimens  
ISO 7539-6:2003 Corrosion of metals and alloys – Stress corrosion testing,  
Part 6: Preparation and use of precracked specimens for tests under constant load or constant displacement  
ISO 7539-7:2005 Corrosion of metals and alloys – Stress corrosion testing,  
Part 7: Slow strain rate testing  
ISO 7539-8:2000 Corrosion of metals and alloys – Stress corrosion testing, Part 8: Preparation and use of specimens to evaluate weldments  
ISO 7539-9:2003 Corrosion of metals and alloys – Stress corrosion testing,  
Part 9: Preparation and use of pre-cracked specimens for tests under rising load or rising displacement  
ISO 8044 1999 Corrosion of metals and alloys – Basic terms and definitions  
ISO 8407:1991 Corrosion of metals and alloys – Removal of corrosion products from corrosion test specimens  
ISO 8565:1992 Metals and alloys – Atmospheric corrosion testing – General requirements for field tests  
ISO 9223:1992 Corrosion of metals and alloys – Classification of corrosivity of atmospheres  
ISO 9224:1992 Corrosion of metals and alloys – Guiding values for the corrosivity categories of atmospheres  
ISO 9225:1992 Corrosion of metals and alloys – Corrosivity of atmospheres – Methods of measurement of pollution  
ISO 9226:1992 Corrosion of metals and alloys – Corrosivity of atmospheres – Methods of determination of corrosion rate of standard specimens for the evaluation of corrosivity  
ISO 9227:2006 Corrosion tests in artificial atmospheres – Salt spray tests

ISO 9400:1990 Corrosion of metals and alloys – Nickel-based alloys – Determination of resistance to intergranular corrosion  
ISO 9591:2004 Corrosion of aluminum alloys – Determination of resistance to stress corrosion cracking  
ISO 10062:2006 Corrosion tests in artificial atmosphere at very low concentrations of polluting gas(es)  
ISO 10270:1995 Corrosion of metals and alloys – Aqueous corrosion testing of zirconium alloys for use in nuclear power reactors  
ISO 10270:1995 Corrigendum 1:1997  
ISO 11130:1999 Corrosion of metals and alloys – Alternate immersion test in salt solution  
ISO 11303:2002 Corrosion of metals and alloys – Guidelines for selection of protection methods against atmospheric corrosion  
ISO 11306:1998 Corrosion of metals and alloys – Guidelines for exposing and evaluating metals and alloys in surface sea water  
ISO 11463:1995 Corrosion of metals and alloys – Evaluation of pitting corrosion  
ISO 11474:1998 Corrosion of metals and alloys – Determination of corrosion resistance through accelerated outdoor atmosphere testing  
ISO 11782-1:1998 Corrosion of metals and alloys – Corrosion fatigue tests, Part 1: Cycles to failure testing  
ISO 11782-2:1998 Corrosion of metals and alloys – Corrosion fatigue tests, Part 2: Crack propagation testing  
ISO 11844-1:2006 Corrosion of metals and alloys – Classification of low corrosivity in indoor atmospheres – Part 1: Determination and estimation of indoor corrosivity  
ISO 11844-2:2006 Corrosion of metals and alloys – Classification of low corrosivity of indoor atmospheres – Part 2: Determination of corrosion attack in indoor atmospheres  
ISO 11844-3:2006 Corrosion of metals and alloys – Classification of low corrosivity of indoor atmospheres – Part 3: Measurement of environmental parameters affecting indoor corrosivity  
ISO 11845:1995 Corrosion of metals and alloys – General principles for corrosion testing  
ISO 11846:1995 Corrosion of metals and alloys – Determination of resistance to intergranular corrosion of solution heat treatable aluminum alloys  
ISO 11881:1999 Corrosion of metals and alloys – Determination of resistance to exfoliation corrosion of high strength aluminum alloys

ISO 11881:1999 Corrigendum 1:1999

ISO 12732:2006 Corrosion of metals and alloys – Electrochemical potentiokinetic reactivation measurement using the double loop method (based on Cihal's method)

ISO 14993:2001 Corrosion of metals and alloys – Accelerated testing involving cyclic exposure to salt-mist, 'dry' and 'wet' conditions

ISO 15324:2000 Corrosion of metals and alloys – Evaluation of stress corrosion cracking by the drop evaporation test

ISO 15329:2006 Corrosion of metals and alloys – Anodic test for evaluation of intergranular corrosion susceptibility of heat-treatable aluminum alloys

ISO 16151:2005 Corrosion of metals and alloys – Accelerated cyclic tests with exposure to acidified salt-spray, 'dry' and 'wet' conditions

ISO 16701:2003 Corrosion of metals and alloys – Corrosion in artificial atmosphere – Accelerated corrosion test involving exposure under controlled conditions of humidity cycling and intermittent spraying of a salt solution

ISO 16784-1:2006 Corrosion of metals and alloys – Corrosion and fouling in industrial cooling water systems – Part 1: Guidelines for conducting pilot-scale evaluation of corrosion and fouling control additives for open recirculating cooling water systems

ISO 16784-2:2006 Corrosion of metals and alloys – Corrosion and fouling in industrial cooling water systems – Part 2: Evaluation of the performance of cooling water treatment programs using a pilot-scale test rig

ISO 17081:2004 Method of measurement of hydrogen permeation and determination of hydrogen uptake and transport in metals by an electrochemical technique
